Nausea, vomiting, abdominal pain, diarrhea, drowsiness, and light-headedness usually occur within a few hours of exposure, regardless of route of exposure. Although liver enzymes may start to rise on the first day after exposure, clinical hepatotoxicity generally occurs on Days 2 to 4, with fever, liver tenderness and enlargement, and jaundice [45]. Decline in renal function may occur concomitantly with hepatic dysfunction, although renal failure occasionally appears in the absence of hepatic failure [46]. Rarely, CCl₄ toxicity is accompanied by coma, convulsions, or myocarditis.

Early fatalities are a result of respiratory depression or cardiac dysrhythmias caused by cardiac sensitization to circulating catecholamines. Later deaths occur as the result of hepatic or renal failure, generally within the first week. In nonfatal cases, liver function tests generally return to normal within 2 weeks; recovery is usually complete.

Treatment initially involves stabilization and monitoring for respiratory depression and cardiac dysrhythmias. Exposure should be interrupted by removing victims of inhalation from the exposure site; in dermal exposures, contaminated clothing should be removed and the skin washed thoroughly. The patients who ingest more than 0.3 mL per kg should undergo gastric aspiration or lavage, preferably within 3 to 4 hours of ingestion [47]. Abdominal radiographs may be helpful in confirming suspected ingestions because CCl₄ is radiopaque [48]. There is no evidence regarding the use of activated charcoal in adsorbing CCl₄. Laboratory evaluation should include a complete blood cell count, routine serum chemistries, liver function tests, and urinalysis. The patients with respiratory symptoms or altered mental status should also be evaluated for possible aspiration pneumonitis, as described for aliphatic hydrocarbon exposures. Although CCl₄ appears not to be well removed by hemodialysis, dialysis may be required in cases of renal failure [49]. Animal studies suggest that hyperbaric oxygen may increase survival
after intragastric administration of $\text{CCl}_4$ [50], although little human data exist on this topic [51]. Additional experimental work is being conducted to examine the utility of $N$-acetylcysteine in the reduction of $\text{CCl}_4$-induced hepatotoxicity. Because toxic intermediates of hepatic P450 are thought to be responsible for $\text{CCl}_4$ toxicity, it is thought that $N$-acetylcysteine may help prevent the development of liver failure [52]. Although human experience with this therapy is extremely limited in this setting and still considered experimental, a dosage schedule identical to that for acetaminophen is generally used.

**Methylene Chloride**

Methylene chloride is a colorless, volatile liquid commonly used as a solvent in aerosol products and as a degreaser and paint remover. It is well absorbed through the lungs and GI tract, but absorption through intact skin appears to be minimal. The majority of a dose is metabolized by the liver to carbon dioxide and carbon monoxide with small amounts exhaled unchanged [53].

The main toxicity of methylene chloride is CNS depression, which results from direct effects and from cellular asphyxia due to elevated levels of carboxyhemoglobin [54]. An 8-hour exposure to 250 ppm of methylene chloride resulted in carboxyhemoglobin fractions greater than 8% [55], and with large exposures, carboxyhemoglobin fractions up to 50% have been reported. In the few cases of methylene chloride ingestion that have been reported, CNS depression, tachypnea, and corrosive injury to the GI tract were the most common findings [56]. When the carboxyhemoglobin fraction is elevated, signs and symptoms of carbon monoxide poisoning may also be evident [57]. Nephrotoxicity and hepatotoxicity have also been reported [58,59].

Treatment involves stabilization, evaluation, and monitoring for aspiration, CNS and cardiovascular depression, dysrhythmias, corrosive injury, carbon monoxide poisoning, and hepatic and renal dysfunction. The patient should be removed from the source of inhalation exposure, and contaminated clothing should be removed. Exposed skin should be washed with soap and water. In cases of ingestion, gastric aspiration, or lavage should be considered. The role of activated charcoal in methylene chloride ingestions is unclear [60]. In all cases, the carboxyhemoglobin fraction as well as complete blood cell count, routine serum chemistries, liver function tests, and urinalysis should be determined and supplemental oxygen provided.

Hyperbaric oxygen is controversial for carbon monoxide poisoning and its role in methylene chloride toxicity is even less clear [61]. It is reasonable to institute hyperbaric therapy when elevated carboxyhemoglobin levels and symptoms of carbon monoxide toxicity are
present. Management is otherwise supportive.

Trichloroethane

1,1,1-Trichloroethane has been widely marketed as a safer alternative to CCl$_4$ for use as a cleaning agent and degreaser. It is also present in typewriter correction fluid and aerosol hairsprays, water repellents, and furniture polishes. In spite of its relative safety, death can occur, usually as a result of occupational or recreational inhalation exposure [62,63].

Trichloroethane is rapidly absorbed through the lungs and GI tract. Under most circumstances, significant cutaneous absorption is unlikely. Distribution is greatest to tissues with a high concentration of lipid, including the CNS. Most of an absorbed dose is excreted unchanged through the lungs, with smaller quantities metabolized in the liver and excreted by the kidneys [7,9].

Toxicity primarily involves the CNS, with signs and symptoms ranging from dizziness, headache, fatigue, and ataxia with mild-to-moderate exposures to seizures, coma, apnea, and death at higher vapor concentrations [64].

As with the aliphatic hydrocarbons, trichloroethane-induced cardiac sensitization to the effects of circulating catecholamines is thought to be responsible for sudden death associated with inhalational exposure [65]. Premature ventricular contractions and ST depression have been observed after acute inhalation [66], and myocarditis has been reported after chronic inhalation abuse [67]. Hepatic and renal toxicities are rare.

Management involves the evaluation and treatment for aspiration, CNS and cardiovascular depression, and dysrhythmias. Decontamination measures may also be appropriate. In the absence of sudden death, recovery is generally rapid and complete.
AROMATIC HYDROCARBONS

Aromatic hydrocarbons contain one or more benzene rings. They include benzene, toluene, xylene, diphenyl, phenol, and styrene. Aromatic hydrocarbons are common constituents of glues, paints, paint removers, lacquers, degreasers, and adhesives. Although the aromatic hydrocarbons have aspiration risks similar to those of the other hydrocarbons, they also exhibit potentially severe systemic toxicity. Exposure is primarily through inhalation (occupational or abuse) or from ingestion. Benzene, toluene, and xylene are the three most commonly encountered agents.

Benzene

Benzene is a colorless liquid used widely in the chemical industry and less commonly as a solvent. It is well absorbed through the lungs and GI tract, but absorption through the skin is limited [68]. The lungs excrete up to 50% of an absorbed dose unchanged, whereas most of the remaining amount is metabolized by hepatic P450 enzymes to potentially cytotoxic metabolites, [69]. Elimination of the parent compound and its metabolites generally occurs within 48 hours.

Benzene has acute and chronic toxicity. Acute exposure primarily causes CNS depression [70]. Initial euphoria is rapidly followed by nausea, dizziness, and headache; subsequent progression to ataxia, seizures, and coma may occur. Persistent symptoms may include insomnia, anorexia, and headache.

Inhalation of high concentrations may lead to development of pulmonary edema; as with other hydrocarbons, aspiration, and cardiac dysrhythmias may develop. Long-term exposure to benzene may result in a depression of bone marrow elements, which may progress to aplastic anemia [71]. Epidemiologic studies also suggest an increased risk of acute myelocytic and monocytic leukemia in workers with prolonged exposure to benzene [72].

Management should focus on stabilizing the patients, and evaluation and monitoring for aspiration, CNS and cardiovascular depression, and dysrhythmias. It is generally agreed that amounts in excess of 1 to 2 mL per kg should be removed from the GI tract (via gastric aspiration or lavage), although some sources recommend removal of virtually any amount. The role of activated charcoal in this setting is unproven [7].
Subsequent therapy is supportive.

Toluene

Toluene is a colorless, volatile, and sweet-smelling liquid that is a common ingredient in paints, paint thinners, lacquers, and glues (e.g., airplane model glue). Although toxicity may occur accidentally in industry or in the household, toluene is one of the most commonly abused solvents [73]. It is highly lipid soluble, and peak blood concentrations occur within 15 to 30 minutes with inhalation [45]. Animal studies suggest that ingested toluene is well absorbed from the GI tract, within 1 to 2 hours after exposure. Absorption through intact skin is slow.

Approximately 20% of an absorbed dose is exhaled unchanged. Most of the remainder is metabolized by the liver’s cytochrome P450 system. Elimination is biphasic, with an initial $\alpha$-phase having a half-life of 4 to 5 hours [74] and representing exhalation combined with distribution to fatty tissues [9]. The $\beta$-phase has an apparent half-life of 15 to 20 hours and represents hepatic metabolism.

Toxic effects involve the CNS and peripheral nervous system as well as the kidney and heart [75]. Electrolyte and metabolic disturbances may also result. Acute exposure to toluene has variable effects on the CNS, depending on the concentration and duration of exposure [73]. Initially, toluene causes intoxication, which can progress to coma with prolonged exposure to high concentrations. Chronic abuse may also lead to persistent signs and symptoms of acute toxicity, including neuropsychiatric symptoms, weakness, nausea, vomiting, peripheral neuropathy, rhabdomyolysis [73], and abdominal pain [8]. Toluene toxicity is associated with a high incidence of renal dysfunction, particularly renal tubular acidosis (i.e., bicarbonate wasting) [73,76]. Laboratory findings include metabolic acidosis (generally without an increased anion gap), electrolyte disturbances (e.g., hypokalemia, hypocalcemia, hypophosphatemia, and hyperchloremia), and hematuria, proteinuria, and pyuria [76]. These abnormalities are the result of tubulointerstitial damage and are generally reversible on cessation of exposure. As with other hydrocarbons, acute toluene inhalation has also been associated with sudden cardiorespiratory arrest [77].

The diagnosis of toluene poisoning is generally made on the basis of the history, with known exposure or solvent abuse the prominent features. Toluene toxicity should also be considered in any individual with altered mental status and metabolic acidosis of unclear cause [78]. Management includes evaluation and treatment for aspiration; CNS and cardiovascular depression; dysrhythmias; renal dysfunction; fluid, electrolyte, and acid–base disturbances; and rhabdomyolysis. Laboratory testing should
include calcium and phosphate levels. Gastric aspiration or lavage may be appropriate in cases of ingestion (with recognition of the aspiration risk).

Xylene

Xylene is a clear liquid that is widely used as a solvent in paints and lacquers, degreasers, adhesives, cleaning agents, and aviation fuel. It is rapidly absorbed by the pulmonary and GI systems and, to some extent, through the skin. The highest concentrations are found in the adrenal gland, bone marrow, spleen, brain, and blood [45]. Small amounts are excreted unchanged through the lungs; most of the remainder is metabolized in the liver and metabolites excreted in the urine. Ethanol consumption causes delays to metabolic clearance of xylene.

Xylene primarily affects the CNS [79]. As with other hydrocarbons, inhalation has been associated with sudden death, presumably secondary to cardiac dysrhythmia [80]. At low doses, headache, nausea, light-headedness, and ataxia may develop; at higher doses, confusion, coma, and respiratory depression may develop. Hepatic damage, Fanconi syndrome, and pulmonary edema have also been described [80,81]. The evaluation and treatment of xylene exposure are similar to that described for other aromatic hydrocarbons.
Terpenes are aliphatic cyclic hydrocarbons. They include turpentine, pine oil, and camphor. Camphor is discussed elsewhere [7,82]. As its name suggests, pine oil is the product of pine trees and composed primarily of terpene alcohols. It is a component in household cleaners (e.g., Pine-Sol, Clorox Company, Oakland, CA), normally present in concentrations of 20% to 35%, but occasionally in concentrations exceeding 60%. Turpentine is a pine tree distillate commonly used as a solvent for paint and varnish.

Toxicity almost always results from ingestion. The aspiration risk appears to be somewhat less than that of other aliphatic hydrocarbons, presumably because of the lower volatility of terpenes; CNS and GI effects are more pronounced, however. Ingestions of more than 2 mL per kg of turpentine are considered potentially toxic [83]. Although 60 to 120 g of pine oil is commonly cited as the lethal dose in adults, survival has been reported after ingestion of 400 to 500 g [84]. The minimal lethal dose of pine oil reported in children is 14 g [85].

Turpentine is well absorbed through the lungs and GI tract [83] and distributed throughout the body, with highest concentrations in the liver, spleen, brain, and kidney [83]. Although the specifics of its metabolism are unclear, turpentine or its metabolites are largely excreted through the kidney. Pine oil is also well absorbed from the GI tract, and after absorption, it is metabolized by the epoxide pathway and excreted in the urine [84]. Although the volume of distribution is unknown, it is thought to be large, with high concentrations in the brain, kidney, and lung.

Manifestations of toxicity include nausea, vomiting, diarrhea, weakness, somnolence, or agitation. In severe cases, stupor or coma may result, although seizures appear to be uncommon [86]. Systemic toxicity, when it occurs, usually develops within 2 to 3 hours of ingestion. In mild and moderate cases, GI and CNS symptoms generally resolve within 12 hours. Turpentine ingestion has been associated with hemorrhagic cystitis, with dysuria and hematuria occurring 12 hours to 3 days after exposure [87].

Management includes the evaluation and treatment for aspiration, gastroenteritis, and CNS depression. The distinctive odors of turpentine and pine oil may provide a clue to diagnosis. Gastric aspiration or lavage is recommended for patients who present within 2 hours of ingesting greater than 2 mL per kg of turpentine or 5 mL of pure pine oil [88]. Because of the risk of aspiration, airway protection should be considered in all but the most alert patients.
The patients who remain asymptomatic or have only mild GI or CNS symptoms 6 hours after ingestion are unlikely to develop serious complications. The patients with pulmonary complications or severe CNS depression require intensive care unit admission and often require ventilatory support.

Hydrofluoric Acid Poisoning
KENNON HEARD

INTRODUCTION

Hydrofluoric acid (HF) is a commonly encountered industrial reagent that is available in the concentrations from 6% to 90%. It is used for the production of fluorocarbons, etching glass, and silicone, and as a household rust-removal agent. Sodium fluoride is used as a rodenticide and also as a preservative in blood collection tubes. A related compound, ammonium bifluoride is used in rust removers, commonly found in commercial car washes.
MECHANISM OF ACTION

HF (pKₐ = 3.8) is a weak acid. Hence, compared with other acids, it is relatively less ionized at any given pH. This allows HF to penetrate more deeply into tissue and to be more readily absorbed into the systemic circulation than other acids. Once absorbed, it disassociates and the fluoride anion binds to divalent cations, forming insoluble salts (primarily calcium fluoride, fluorapatite, and magnesium fluoride). This results in tissue and systemic hypocalcemia and hypomagnesemia. Fluoride also directly poisons several enzymes and cellular transport proteins. High-concentration HF exposures result in rapid onset of local pain and tissue injury with or without systemic toxicity, whereas low-concentration exposures can result in life-threatening hypocalcemia and hypomagnesemia, with minimal or absent local corrosive effect.
DERMAL EXPOSURE

Clinical Manifestations

Although most dermal exposures will result in minor symptoms or superficial chemical burns, systemic toxicity may occur following dermal exposure. Symptoms may be delayed for 24 hours or more following low-concentration (<20% HF) exposure, and there is often severe pain with minimal skin abnormalities. Symptoms can develop within several hours of exposure to medium concentrations (20% to 50% HF). Although the initial injury is not always visible, the patients exposed to medium-concentration products often go on to have erythema, blanching, or necrosis of the involved area. High-concentration (>50% HF) exposures result in the immediate injury expected after exposure to concentrated acids. The patients may develop full- or partial-thickness injury that includes tissue necrosis and eschar formation [1].

Evaluation and Treatment

Laboratory studies are not indicated for small, low-concentration dermal exposures. However, exposure to products containing more than 50% HF that involve more than 1% of the skin or exposure to any HF product that affects more than 5% of the skin can cause hypocalcemia, so the patients with these burns should have serum calcium levels monitored, as described in the ‘Systemic Toxicity’ section [2].

The most important step in the treatment is decontamination by irrigating the affected area for at least 15 minutes as quickly as possible. In one large case series of exposures, many of which involved concentrations of greater than 40% HF, immediate irrigation produced excellent outcome in the majority of the patients [3]. Hexafluoride, an irrigating solution developed to bind fluoride, does not appear to offer any improvement over water irrigation [4].

After irrigation, apply a 2.3% to 2.5% calcium gluconate preparation in a water-soluble gel to the exposed areas for at least 30 minutes or until symptoms resolve [5]. This treatment often remains effective, if it is delayed several hours after symptoms develop [6]. The role of topical therapy following high-concentration exposures is less well defined, but it is recommended [7].

If pain is not relieved by topical therapy, regional intra-arterial or intravenous calcium perfusion should be initiated. The major drawback of intra-arterial perfusion is the requirement for arterial catheterization. Brachial, radial, and femoral catheterization have all been described.
Following cannulation, monitor arterial waveform to assure that the catheter remains patent and properly placed within the artery. If there is any question as to adequate placement, performs arteriography prior to infusing calcium. Flushing the catheter with heparin may help keep the catheter patent [2]. The largest case series reported infusion of 50 mL of 2.5% calcium gluconate in saline over 4 hours [2]. It is not uncommon to have to repeat the dose several times over a 12- to 24-hour period.

Regional perfusion using a Bier block may allow treatment without arterial cannulization. Some clinicians advocate this technique before proceeding to intra-arterial administration. This technique requires venous cannulation in the affected extremity. The extremity is exsanguinated by elevation and compression with an Esmarch bandage. The blood pressure cuff should be inflated to a pressure of 100 mm Hg above systolic pressure and remain up for 15 to 20 minutes following calcium administration. The usual dose is 40 mL of a 2.5% calcium gluconate solution [8]. The cuff is then gradually deflated over 5 minutes. Pain is usually relieved within minutes of the calcium administration.

If the affected area is not an extremity, calcium can be directly injected into the burn. The most common method is injection of 0.3 to 0.5 mL per cm$^2$ of 2.5% calcium gluconate. Calcium chloride should not be used, because it can cause tissue injury. Excision of exposed tissue is not recommended.
OCULAR EXPOSURE

Clinical Manifestations

Although most human reports describe good outcomes following ocular HF exposure, animal studies have demonstrated that severe injury is possible. Although most patients have rapid onset of pain, HF can penetrate the eye and cause severe and delayed injury.

Evaluation and Treatment

Immediate irrigation is the most important treatment. Irrigation with calcium salts appears to offer no benefit over saline in animal models, and may increase the incidence of ulceration [9]. Following irrigation, the pH should be measured and a fluorescein examination should be performed. All patients with persistent symptoms or obvious corneal damage should have immediate evaluation by an ophthalmologist. Some will require admission for continuous irrigation. The patients who are asymptomatic after irrigation should have next-day follow-up with an ophthalmologist. Routine therapy for corneal burns from HF has included mydriatics, topical antibiotics, and steroids [10–12]. Treatment of these burns with calcium gluconate eyedrops has been suggested, but systematic human studies have not been reported [12].
INHALATION

Clinical Manifestations

Inhalation of HF may result in the severe airway injury, pulmonary injury, and systemic fluoride poisoning. The patients may present with severe or minimal symptoms and go on to develop complications over time [13]. Although systemic fluoride poisoning may occur [14], the major mechanism of pulmonary injury is acute lung injury.

Evaluation and Treatment

Following inhalation of HF, the patients should have chest radiographs, evaluation of oxygenation, and monitoring for hypocalcemia. Treatment is supportive, and early airway intervention may be required for the patients with symptoms of upper airway obstruction. There are several uncontrolled reports of good outcomes following treatment with nebulized calcium gluconate solution (2.5% to 5.0%) [15,16].
INGESTION

Clinical Manifestations

Oropharyngeal burns are rarely noted, even in fatal poisonings [17]. Although gastrointestinal symptoms such as nausea, vomiting, and gastritis may occur, the primary manifestation of oral HF exposures is systemic fluoride toxicity (see below). Following accidental sip ingestions, the patients who are able to swallow should be given 30 to 60 mL of water to drink to dilute any HF still in contact with the esophageal mucosa. Although it is commonly recommended to administer calcium or magnesium antacids, animals studies have found that very high doses are required to affect mortality [18,19]. The patients with accidental ingestion of products containing more than 7% HF or deliberate ingestion of any HF or ammonium fluoride product are at risk for systemic poisoning and require continuous cardiac monitoring, reliable vascular access, and close monitoring of serum calcium levels, as described in the next section.

Systemic Toxicity

Systemic fluoride toxicity may occur following inhalation, dermal, or oral exposure to HF-containing products. Although the exact mechanism of fluoride toxicity requires continued research [20], human cases of fatal HF toxicity consistently demonstrate profound hypocalcemia [21]. Other manifestations include hypomagnesemia, acidosis, and hyperkalemia. Minimally symptomatic patients may progress rapidly to cardiovascular collapse [22].

Because successful resuscitation from cardiac arrest following systemic fluoride poisoning is rare, treatment should be started early to prevent cardiac dysrhythmias and arrest. The patients should have continuous cardiac monitoring, reliable vascular access, and frequent measurement of serum calcium and magnesium levels. If the history suggests that there has been a significant exposure, prophylactic calcium should be initiated at a rate of 1 g over 30 minutes [20]. The patients who have normal vital signs and remain stable should have serum calcium levels monitored every 30 minutes for the first 2 to 3 hours. Calcium chloride 1-g boluses should be repeated as needed to maintain the serum calcium in the high normal range. The patients with hypocalcemia, dysrhythmias, or hypotension should receive 2 to 3 g of calcium every 15 minutes, and central venous access should be obtained. Successful treatment of cardiac arrest has generally been associated with administration of large doses (>10 g) of calcium. Intravenous magnesium sulfate 2 to 6 g over 30
minutes followed by a continuous 1- to 4-g infusion has also been suggested.

Beyond calcium and magnesium administration, fluoride-poisoned patients require aggressive supportive care. The patients with symptoms of airway involvement should be intubated. Similarly, ventilation and oxygenation problems are rare but should be treated promptly when present. Successful electrical cardioversion for dysrhythmias following calcium and magnesium therapy has been reported [23].

A therapy that is unproven but has theoretical benefit is serum and urine alkalization. One animal study showed that systemic alkalosis increased the fatal fluoride dose in rats [24]. Although this study has obvious limitations, serum alkalization should be considered in critically ill patients. However, over alkalization may worsen hypocalcemia; therefore, serum pH should be maintained between 7.4 and 7.5. Although fluoride is cleared by hemodialysis, the patients with severe poisoning may be too unstable to tolerate dialysis.
REFERENCES

Iron poisoning is the most common cause of poisoning death in children younger than 6 years [1]; however, morbidity and mortality have decreased secondary to unit-dose packaging of iron supplements [2]. Notably, a clinically important proportion of iron overdoses is purposeful, involving adolescents and adults, and resulting in significant morbidity and mortality [3].

Iron occurs naturally in the body. It is highly reactive, and there are complex mechanisms for its absorption, transport, and storage. The capacity of these systems to cope with an acute overdose is unknown; it likely varies from individual to individual and with the state of iron stores. Incomplete understanding of iron toxicokinetics is primarily responsible for controversies regarding (a) toxic dose; (b) gastrointestinal decontamination; (c) efficacy of intragastric complexation therapies; and (d) the indications, dose, duration, and efficacy of deferoxamine therapy.

PHARMACOLOGY

Iron is readily available as ferrous salts, either alone or in combination with other minerals and vitamins. Its common salts are ferrous gluconate, sulfate, fumarate, and succinate, which are 12%, 20%, 33%, and 35% elemental iron, respectively. These fractions are important because toxicity is related to the amount of elemental iron ingested. Carbonyl iron is a highly purified form of metallic iron. It is uncharged and not a salt [4].

Iron absorption, transport, and storage are well reviewed elsewhere [5]. Because there is no endogenous mechanism for iron excretion, total body iron is a function of the absorptive process. Absorption occurs in the proximal small bowel, with approximately 10% of the ingested dose absorbed, but with 10-fold variations, depending on iron stores and the amount ingested. The actual mechanism of iron absorption is not well
understood, but it is believed to be an active process. Even after massive overdose, a relatively small amount (15%) is actually absorbed [6].

Peak serum iron concentrations occur within 4 to 6 hours after overdose. The half-life after therapeutic dosing is approximately 6 hours [5], with rapid decline because of tissue distribution. In plasma, iron is bound to transferrin, a specific $\beta_1$-globulin responsible for iron transport throughout the body. In iron overdose, transferrin-binding capacity is exceeded, but free plasma iron does not truly exist. Iron complexes with other plasma proteins and organic ligands and is referred to as nontransferrin-bound plasma iron [7]. However, it is only loosely bound and is quite available to produce tissue damage and organ dysfunction.

There are two typical overdose scenarios: innocent overdose by young children and purposeful overdose by adolescents and adults. Serious iron overdose in young children frequently involves the ingestion of a product intended for adults, typically a prenatal iron supplement. Ingestion of pediatric preparations, such as multivitamin plus iron tablets, is more common [8]; such preparations are unlikely to result in significant toxicity because of their low elemental iron content (as little as 4 mg per tablet). Although liquid iron preparations are often found in homes with infants and toddlers, there are no published cases of clinically important iron poisoning from these products. Iron overdose is less common among teenagers and adults, but when it occurs, it is typically more severe. Of particular note is the high incidence of deliberate iron overdose in pregnant women [9].

Iron exerts both local and systemic effects. The local irritant effect on the gastrointestinal tract results in nausea, vomiting, abdominal cramps, and diarrhea. These symptoms are produced by relatively small doses (20 mg per kg of elemental iron). The extent of systemic toxicity is dose related. Because most published data are anecdotal, specific values have not been established. In the pediatric literature, more than 60 mg per kg of elemental iron produces significant systemic toxicity [10], with a lethal dose being 200 to 250 mg per kg [10]. Both the figures are likely overestimates; more realistic figures are probably half as much. The lowest reported lethal dose for a toddler is approximately 75 mg per kg of elemental iron [11]. The author’s own experience and that of others [12] suggests that the toxic dose in adults is similar to that in children. An ingestion of 1.5 g of elemental iron by an adult should be cause for concern. Adults have died after ingestion of as little as 2 g [13] and 5 g [12] of elemental iron; the former patient had significant hepatic disease, and the latter ingested 70 mg per kg. There have been no published
reports of serious or fatal poisoning from the ingestion of carbonyl iron products [4]. Although its bioavailability after therapeutic dosing is similar to that of ferrous salts, its absorption is limited after an overdose. Single doses of 10 g (140 mg per kg) have been tolerated in humans.

Poor, unpredictable absorption of iron and its unknown capacity for binding by ferritin and as hemosiderin contribute to uncertainty regarding the toxic dose. As reflected by serum iron concentrations, which are measured in micrograms per deciliter, the size of the potentially toxic iron pool is likely to be small—on the order of milligrams—even after gram quantities of iron have been ingested. That the body burden of iron is relatively small after an overdose is not well appreciated, but it has important implications for the dose and duration of deferoxamine therapy.

Iron itself is neither caustic nor corrosive. It is a potent catalyst of free radical formation, which results in highly reactive species that attack intracellular molecules [14]. Iron-generated free radical formation is thought to contribute to acute iron toxicity [15] and to be responsible for much of the damage and dysfunction of chronic iron overload [7].

Free radicals produce damage at their site of origin. Because of local protective mechanisms, a significant concentration of free radicals is required to cause damage. Sites exposed to high iron concentrations are most susceptible to injury. One such area is the gastrointestinal tract. Gastrointestinal mucosal necrosis and bleeding [16] may occur without systemic toxicity. Notably, gut toxicity can occur distally with proximal sparing [16] and may be absent in the face of fatal systemic poisoning [6].

Systemic toxicity results when the absorbed iron is transported to target organs, such as the liver and heart. Nontransferrin-bound iron is rapidly cleared by the liver [17], putting this organ at risk for toxicity [18].
CLINICAL TOXICITY

Traditionally, acute iron intoxication is divided into five clinical stages [19]: gastrointestinal toxicity, relative stability, circulatory shock, hepatic necrosis, and gastrointestinal scarring. An orderly progression through all these stages may not occur. Fatalities are possible without significant gastrointestinal involvement [6], and hepatotoxicity may be absent in otherwise severe poisoning. Presenting symptoms and signs depend on the time since ingestion.

The most common time of presentation is during the first stage (gastrointestinal toxicity), when abdominal pain, vomiting, diarrhea, hematemesis, and hematochezia can be seen. Gastrointestinal toxicity usually occurs within the first few hours of overdose. The severity of this stage is variable. Life-threatening hypovolemic shock may occur, especially if initial symptoms were severe or ignored. Occasionally, segmental intestinal infarction may occur, necessitating bowel resection [16]. Isolated hepatotoxicity or gastrointestinal obstruction would be an unlikely presentation of iron poisoning.

The second stage, a period of relative stability, follows initial gastrointestinal symptoms. Apparent improvement in the patient’s clinical status should not lead to complacency. Patients are not completely asymptomatic; careful assessment and repeated monitoring typically shows some degree of hypovolemia, hypoperfusion, and acidosis.

The third stage, circulatory shock, can occur within several hours of iron overdose and may persist up to 48 to 72 hours. Its pathogenesis is complex and poorly understood and is based on the results of limited experimental animal data [20-23]. Circulatory shock may be hypovolemic, distributive, or cardiogenic. The time of onset can be somewhat helpful in elucidating its cause, but there is considerable overlap. Shock occurring within a few hours of the overdose suggests hypovolemia secondary to fluid and, rarely, blood loss from the gastrointestinal tract. Hyperferremia-associated coagulopathy may contribute to bleeding [24]. Distributive shock depends on iron absorption and begins within the first 24 hours. Suggested mechanisms include direct effects of iron or ferritin or an effect mediated by release of vasoactive substances, resulting in decreased vascular tone or increased vascular permeability [22]. Cardiogenic shock usually occurs 1 to 3 days after overdose [25].

The occurrence of metabolic acidosis in iron poisoning usually precedes circulatory shock. Acidosis is a direct toxic effect of iron that occurs after the plasma’s capacity to bind the absorbed ferric ion has been
exceeded. When this occurs, the ferric ion becomes hydrated and protons are released \([\text{Fe}^{3+} + 3\text{H}_2\text{O} \rightarrow \text{Fe(OH)}_3 + 3\text{H}^+]\). Thus, each unbound ferric ion generates three protons. The acidosis can be quite profound, requiring large amounts of bicarbonate for treatment [23]. Other factors contributing to acidosis include the generation of organic acids resulting from iron’s interference with intracellular oxidative metabolism and lactate production secondary to shock.

The fourth stage, hepatotoxicity, is second only to shock as a cause of death [18]. It may occur any time during the first 48 hours after overdose. The pathogenesis of hepatic necrosis is believed to be iron-catalyzed free radical production and subsequent lipid peroxidation of hepatic mitochondrial membranes [15].

The fifth stage, gastrointestinal scarring, is the consequence of iron’s local action on the gut and usually occurs 2 to 4 weeks after overdose. Ongoing and protracted abdominal pain during the first week is associated with the later development of this complication [16]. Most cases involve the gastric outlet, but isolated strictures of the distal intestine have been reported [16].

The consequences of iron poisoning in pregnant women are no different from those in other patients, but because transplacental iron passage is an energy-requiring saturable process, the fetus is relatively protected [26]. Although deferoxamine in animals is associated with potential harm to the fetus, its risk in humans is overemphasized [26]. The health of the fetus depends on its mother, and treatment should be no different from that given to a nonpregnant woman.
DIAGNOSTIC EVALUATION

Essential laboratory tests include abdominal radiographs, serum iron and bicarbonate concentrations, and blood gas determinations. Because iron tablets are radiopaque, an abdominal radiograph can be used to verify an overdose and quantify the amount ingested [27–29]. However, iron tablets may not be visible if they have dissolved or been chewed, a liquid preparation has been ingested, or there is only a small amount of iron in each tablet (e.g., pediatric iron-containing multivitamins) [30]. If tablets are visible, serial abdominal radiographs may be used to judge the effectiveness of gastrointestinal decontamination.

Serum iron concentration is the single most important test. It verifies the ingestion, guides management, and provides prognostic information. A peak serum concentration of less than 500 μg per dL (90 μmol per L) is usually associated with negligible-to-mild systemic toxicity; however, there may be significant gastrointestinal symptoms. Moderate systemic toxicity is expected with a peak concentration of 500 to 1,000 μg per dL (90 to 180 μmol per L). A peak serum concentration greater than 1,000 μg per dL (180 μmol per L) is associated with severe toxicity, such as profound acidosis, shock, hepatotoxicity, coma, and death. Mortality approaches 100% when serum concentration is greater than 10,000 μg per dL (1,800 μmol per L). The time of blood sampling to estimate peak serum iron concentration should be 4 to 6 hours after an overdose. Serial serum iron concentration determinations are recommended during the early hours after overdose, especially when the first value is 300 to 500 μg per dL (55 to 90 μmol per L). Determinations should be obtained every 2 hours until a definite downward trend is established. A concurrent abdominal radiograph may be helpful. If many tablets are visible, the subsequent serum iron concentration will likely be higher. However, a negative radiograph does not guarantee that peak serum iron concentration has occurred. It is desirable to obtain blood specimens before initiating deferoxamine therapy because it can confound the laboratory determination of serum iron concentration, resulting in falsely lower values [31]. When clinically indicated, deferoxamine therapy should not be delayed because of blood sampling issues.

Blood gas or serum bicarbonate determinations should be done early because acidosis is an early objective indicator of systemic toxicity. Frequency of blood gas determinations is guided by previous values, the
need for bicarbonate therapy, and clinical course. A pH of less than 7.30 indicates significant toxicity.

Recommended laboratory tests include blood coagulation, hepatic, and renal panels. Coagulation studies should be done early and repeated throughout the first few days in patients with significant toxicity because a biphasic coagulopathy may develop [24]. Blood should be typed and cross-matched as clinically indicated. Hepatic panels should be monitored daily during the first 72 hours and longer if values remain significantly abnormal. Renal panels should be obtained regularly, especially during deferoxamine therapy, because of the risk for acute renal failure [32].

The total iron-binding capacity (TIBC) is not recommended in the assessment or management of patients with iron overdose because it is unreliable during hyperferremic states and it does not predict iron toxicity [33]. It is difficult to accurately predict outcomes because the published literature chiefly consists of anecdotal reports. Survival is expected with peak serum iron concentrations of less than 1,000 μg per dL (180 μmol per L) and appropriate supportive care. The chief causes of death are shock and hepatic failure. Acute renal failure may result from shock or deferoxamine therapy without adequate volume replacement [32]. Yersinia septicemia has been reported in patients treated with deferoxamine [27,34].

Differential diagnosis becomes an issue only when the history of iron overdose is unknown. In such situations, diagnosis can be quite challenging because of the multiple and varied clinical features at presentation (e.g., abdominal pain, gastrointestinal hemorrhage, shock, and coma). From the poisoning perspective, corrosive ingestion and acute heavy metal poisoning are the main considerations.
MANAGEMENT

The initial management of a patient with an iron overdose presents a challenge because the patient often presents before maximal clinical toxicity. Many patients, especially young children, may be asymptomatic or only mildly ill. The challenge lies in identifying those who are destined to suffer significant toxicity in order to place them in an appropriate setting for the required level of care. The decision for the iron-overdosed critically ill patient is straightforward. Table 115.1 provides guidelines for intensive care unit admission for those patients who are not critically ill.

Not all criteria need to be present.

\(^a\) Assuming 60-mg elemental iron/tablet.

Because activated charcoal does not adsorb iron [28], whole-bowel irrigation (WBI) (Fig. 115.1) is recommended as the decontamination procedure of choice for the iron-overdose patient [29]. WBI should be considered when there is radiographic documentation of iron ingestion and when there is a history of elemental iron ingestion greater than 60 mg per kg in children and 1.5 g per kg in adults. If emesis hampers effective WBI, consider metoclopramide (1 mg per kg intravenously in adults and 0.1 mg per kg in children) or ondansetron (8 mg per kg
intravenously in adults or 0.1 to 0.2 mg per kg in children).

**FIGURE 115.1** Abdominal radiograph of a 16-year-old girl with a potentially lethal iron overdose after syrup of ipecac-induced emesis and gastric lavage. Gastroscopy ruled out adherence of iron to the stomach wall and medication concretion. She subsequently underwent whole-bowel irrigation. Her peak serum iron concentration was 253 μg per dL (46 μmol per L), and she was not treated with deferoxamine.

Iron can become adherent to the gastrointestinal mucosa or may form tablet bezoars [35]. Radiographs in three planes (flat, upright, and decubitus) should identify these two situations. A computed tomographic (CT) scan is another consideration. Barium studies are unlikely to be helpful because of the anticipated lack of contrast between barium and iron. If WBI is ineffective, removal of iron via gastrotomy should be considered [35,36]. For surgical intervention to be effective, it should be done before the iron is absorbed, and most tablets must be in a localized area rather than scattered throughout the gastrointestinal tract. A combined approach of gastrotomy for tablet retrieval followed by WBI after surgery has been described [36]. The former removed the iron from the stomach, and the latter removed it from the intestinal tract. Endoscopic removal of an iron bezoar from the stomach has been reported [37].
The oral administration of bicarbonate, phosphate, or deferoxamine is not recommended. These agents have been advocated as a way to decrease iron absorption by precipitating it as an insoluble salt or by chelating it. In vitro [38] and animal [39] studies do not support bicarbonate or phosphate administration, and the latter therapy has resulted in hypocalcemia and hypovolemia in iron-overdosed patients [40]. Oral deferoxamine is not recommended. It is neither appreciably toxic nor absorbed from the gastrointestinal tract, but the same is not true of its chelate, ferrioxamine [19,21,41]. The latter has been shown to be lethal in animals [21,42].

Supportive care should be provided concurrently with gastrointestinal decontamination. In patients with severe poisoning, two intravenous (IV) lines are required: one for fluid resuscitation and bicarbonate administration and the other for deferoxamine therapy. Very large amounts of crystalloid and bicarbonate may be required [23], and occasionally, colloid or blood may be necessary. Because of the complex nature of shock in iron poisoning, assessment of cardiac output or myocardial contractility by ultrasound may be helpful. Early shock should respond to vigorous volume resuscitation; occasionally, pressor therapy may be needed. Late shock usually requires inotropic support. An arterial catheter for frequent blood gas determinations and a Foley catheter for monitoring urine output are essential in all critically ill patients.

Parameters requiring serial monitoring include arterial blood gas; hematocrit; serum electrolytes; and renal, hepatic, and blood coagulation panels. The frequency of these determinations depends on previous results and the patient’s clinical condition and response to therapy.

Acute hepatic failure is managed by standard protocols. Acute renal failure may be a consequence of shock or deferoxamine therapy in the setting of hypovolemia [32]. Hemodialysis may be required in such situations, especially if deferoxamine therapy is continued, to remove the toxic chelate, ferrioxamine. Coagulopathy during the first few hours after overdose is related to serum iron concentration and is transient. Specific therapy is unnecessary. Deferoxamine lowers the serum iron concentration and may hasten its resolution [24]. Coagulopathy occurring many hours to a few days after overdose is a manifestation of hepatic failure. Administration of fresh-frozen plasma is recommended, because vitamin K1 is unlikely to be helpful.

Hemodialysis or hemoperfusion is not recommended for iron removal because of the rapid extravascular distribution of the iron and its binding to plasma proteins as non–transferrin-bound iron [7]. However, hemodialysis is indicated for patients with renal failure.

Deferoxamine, the specific treatment of choice for acute iron poisoning [15,19], is a naturally occurring siderophore isolated from *Streptomyces pilosus*. Its pharmacology was described in the early 1960s [43,44]. Its
binding constant for ferric iron is $10^{31}$, which compares with $10^{27}$ to $10^{29}$ for transferrin. It is capable of removing iron from ferritin and hemosiderin and, to a very minor degree, from transferrin, but not at all from cytochromes, hemoglobin, or myoglobin.

Although deferoxamine is regarded as the treatment of choice, its effectiveness has been questioned because it has limited chelating capacity and only small amounts of iron are recovered in the urine after its administration to iron-poisoned patients [45]. The manufacturer’s recommended daily deferoxamine dosage of 6 g is capable of chelating 510 mg of iron or 8.5 ferrous sulfate tablets. Although this would seem to be insignificant in the patient who has ingested 50 tablets, the poor absorption of iron and the body’s large storage capacity for it result in only a relatively small amount being responsible for toxicity. Therefore, the chelation of small amounts of iron may be beneficial. Alternatively, 510 mg of iron is approximately 10% of the total amount of iron and approximately 35% of the nonheme iron in a 70-kg man [46].

Historically, therapy was based on the deferoxamine chelation challenge test and relied on visual detection of a change in urine color to rusty orange (vin rosé) caused by the presence of ferrioxamine after intramuscular administration of deferoxamine. This test has never been validated and is not recommended.

Traditional indications for deferoxamine therapy have been based on the peak serum iron concentration, the serum iron concentration relative to the TIBC, the results of a chelation challenge test, and the patient’s clinical condition. The therapy has been recommended for those with peak serum iron concentrations ranging from 300 to 500 μg per dL (55 to 90 μmol per L) [47]. Significant morbidity is unlikely with peak concentrations of less than 500 μg per dL (90 μmol per L). Hence, a serum iron concentration of 500 μg per dL (90 μmol per L) or greater is recommended as an indication for deferoxamine therapy in an otherwise asymptomatic patient. Deferoxamine therapy is indicated when symptoms and signs of severe iron poisoning are present, regardless of the serum iron concentration. These include acidosis, shock, and decreased level of consciousness or coma. Although some toxicologists also advocate deferoxamine therapy for those with recurrent vomiting or diarrhea, these symptoms can be seen in patients who do not develop systemic toxicity.

Deferoxamine should be administered intravenously. The patient should be fluid resuscitated prior to IV deferoxamine therapy, which should be initiated slowly and gradually increased to 15 mg per kg per hour for 20 to 30 minutes. Continuous IV infusion is the recommended method for administering deferoxamine. This is based on studies in patients with transfusion-induced iron overload, demonstrating that IV deferoxamine results in greater urinary iron elimination, higher peak and
more stable serum deferoxamine concentrations [48].

The optimal dose of deferoxamine is uncertain. The manufacturer recommends a daily maximum dose of 6 g given in divided doses. A continuous infusion protocol of 15 mg per kg per hour until 24 hours after the urine returns to its normal color has also been recommended [15]. The latter protocol exceeds the manufacturer’s guidelines for patients heavier than 17 kg. Neither recommendation is evidence based. Only two patients treated with 15 mg per kg per hour over a prolonged course have been well described in the literature [49,50]. Furthermore, continuous IV deferoxamine therapy in patients with acute iron poisoning for longer than 24 to 48 hours has been associated with the development of adult respiratory distress syndrome [51]. Four patients with mild-to-moderate iron poisoning without evidence of shock, acidosis, or sepsis who received 15 mg per kg per hour of deferoxamine intravenously for 2 to 3 days died of noncardiogenic pulmonary edema [51]. Continuous IV deferoxamine therapy should not routinely exceed the first 24 hours. If prolonged chelation therapy is deemed necessary, interrupting therapy for 12 of every 24 hours to allow excretion of ferrioxamine can be considered. Careful monitoring of pulmonary status is required during prolonged therapy.

Indications for discontinuing deferoxamine therapy include resolution of the symptoms and signs of systemic iron toxicity and correction of acidosis. Deferoxamine therapy is rarely needed beyond 24 hours and should be used with caution for periods longer than this.

Adverse drug events from short-term deferoxamine therapy are few, but significant. Rapid IV administration is associated with tachycardia, hypotension, shock, a generalized beet-red flushing of the skin, blotchy erythema, and urticaria. Acute renal failure can result when deferoxamine is administered to patients with hypovolemia [32]. Pulmonary toxicity and acute respiratory distress syndrome are associated with continuous IV therapy over several days [51]. Patients receiving deferoxamine may be at increased risk for Yersinia infections [27,34].

Before discharge, a psychiatric assessment is indicated for all patients with purposeful ingestions. Those who have required deferoxamine therapy should have a follow-up visit approximately 1 month after discharge. At this time, the patient’s iron status and gastrointestinal tract should be assessed. He or she should also be advised of the symptoms of gastrointestinal obstruction and to return immediately if they occur. Chronic hepatic or cardiac dysfunction has not been reported after acute
iron overdose.

1976.

Isoniazid Poisoning
JAMES B. MOWRY • R. BRENT FURBEE

Isoniazid (isonicotinic acid hydrazide [INH]) is the cornerstone of treatment and prevention of tuberculosis. It is available under a variety of brand names as 50-, 100-, and 300-mg tablets; as an oral syrup (50 mg per 5 mL); as an injectable solution (100 mg per mL); and in powder form. It is also available in combination with rifampin, pyridoxine, and other antitubercular drugs.

In 2013, the American Association of Poison Control Centers reported 149 cases with exposure to INH, including 104 single exposures; 44% of the cases involved adults or adolescents, with 21% being intentional. No deaths were reported, but 21% of the cases exhibited moderate-to-severe toxicity.

PHARMACOLOGY

As a bactericidal agent, INH interferes with lipid and nucleic acid biosynthesis in the growing Mycobacterium organism. It is rapidly and almost completely absorbed after oral administration, with peak plasma concentrations occurring within 1 to 2 hours [1]. The rate and extent of absorption are decreased by food. The volume of distribution of INH approximates total body water (0.67 ± 0.15 L per kg), with cerebrospinal fluid concentrations 90% of those of serum [2]. INH passes into breast milk and through the placental barrier. There is little protein binding.

Between 75% and 95% of an INH dose is acetylated in the liver within 24 hours by N-acetyltransferase 2 (NAT2) to acetylisoniazid and by hydrolysis to isonicotinic acid and hydrazine [1]. In addition, variable amounts of both INH and acetylisoniazid are oxidized by CYP2E1 to hepatotoxic intermediaries [3]. Genetic variation of the enzymes responsible for its metabolism causes significant variations of plasma concentration, elimination half-life, and toxicity. The elimination half-life in rapid acetylators (e.g., Asians, Eskimos, and American Indians) is 0.5
to 1.5 hours, whereas it is 2 to 4 hours in slow acetylators (e.g., people of African descent and Caucasians) [4]. The elimination half-life can be prolonged in people with liver disease. Rapid acetylators excrete 2.5% of INH as unchanged drug, compared with 10% in slow acetylators [1]. In addition, slow acetylators may have a higher percentage of the dose metabolized to hydrazine, a potential hepatotoxin [5]. INH exhibits dose-dependent inhibition of the mixed-function oxidases CYP2C19 and CYP3A, increasing the risk of adverse drug reactions in slow acetylators during the coadministration of drugs metabolized by these enzymes (e.g., phenytoin, carbamazepine, and diazepam).

Acute ingestion of 1.5 to 3.0 g in adults may be toxic, with 6 to 10 g uniformly associated with severe toxicity and significant mortality [6]. In patients with preexisting seizure disorders, convulsions have occurred with therapeutic dosing at doses as low as 14 mg/kg/d; 19 mg/kg/d resulted in seizures in a 7-year-old child [6].

Daily therapeutic INH doses produce peak serum concentrations between 1 and 7 μg per mL. Intermittent INH therapy may produce concentrations between 16 and 32 μg per mL. Serum INH concentrations in acute ingestions have ranged from 20 μg per mL to more than 710 μg per mL, with little correlation to severity of intoxication [7–10].

The central nervous system toxicity of INH and its metabolites is believed to be due to a decrease in the concentration of γ-aminobutyric acid (GABA), an inhibitory neurotransmitter that suppresses neuronal depolarization by opening chloride ionophores (Fig. 116.1). INH combines with pyridoxine (vitamin B₆) and is excreted in the urine as pyridoxal isonicotinylhydrazine [11]. It also competes with pyridoxine for pyridoxine kinase, the enzyme that converts pyridoxine to pyridoxal 5′-phosphate, the cofactor for glutamic acid decarboxylase–mediated conversion of glutamate to GABA [12]. In addition, INH inhibits glutamic acid decarboxylase activity. Its metabolism results in metabolites such as hydrazides and hydrazones, which inhibit pyridoxal 5′-phosphate and pyridoxine kinase, respectively [13].
INH causes a peripheral neuropathy that may be responsive to pyridoxine supplementation [14]. Wallerian degeneration of the myelin sheath and axon with blockade of fast axoplasmic transport is noted, with sensory nerves affected more than motor nerves. Peripheral neuropathy is most commonly associated with chronic INH use in slow acetylators but may occur after acute massive overdose [15,16].

The mechanism of INH-induced hepatic injury is not completely understood. Hepatitis occurs in 0.1% to 1.1% of patients receiving INH, especially those with advanced age and alcohol consumption [17–20]. Concurrent rifampin therapy increases the incidence of hepatitis to 2.7% in adults and 6.9% in children [17–21]. It is unclear whether this effect is due to an influence of rifampin on INH metabolism, or to the additive effect of two hepatotoxic drugs [19]. The histopathologic pattern of hepatic injury closely resembles viral hepatitis. Hypersensitivity seems unlikely, as rechallenge often fails to produce recurrence. Hepatic damage may be due to hydrazine metabolites of INH that covalently bind to liver macromolecules resulting in necrosis [22]. The severity of hepatotoxicity may be related to high-activity genotypes of CYP2E1 producing increased concentrations of reactive metabolites [3]. Recent work suggests that slow acetylators are more susceptible to antitubercular drug–induced hepatitis and may develop more severe hepatotoxicity than do rapid acetylators [3]. Additional risk factors may include homozygous null mutations in GSTM112 or GSTT113, the absence of HLA-DQA1*0102, and the presence of HLA-DQB1*0201 alleles [3].

The severe metabolic acidosis seen in acute INH intoxication is almost entirely due to seizure activity [23]. Although INH may interfere with nicotinamide adenine dinucleotide (NAD)–mediated conversion of lactate to pyruvate, acidosis was not observed in animal studies until seizures occurred with lactic acidosis resolving within 2 hours of cessation of seizures [23]. \(\beta\)-hydroxybutyric acid production has also been reported following INH overdose, but does not appear responsible for INH-induced acidosis.

Hyperglycemia may result from disruptions of the Krebs cycle that require NAD and from stimulation of glucagon secretion [9].
CLINICAL PRESENTATION

Signs and symptoms usually appear within 30 minutes to 2 hours following an acute INH overdose. Nausea, vomiting, dizziness, slurred speech, blurred vision, and visual hallucinations (e.g., bright colors, spots, and strange designs) are among the first manifestations [6,7]. Stupor and coma can develop rapidly, followed by intractable tonic-clonic generalized or localized seizures, hyperreflexia or areflexia, and cyanosis [6,7]. In severe cases, cardiovascular and respiratory collapse results in death. Oliguria progressing to anuria has been reported [6]. The metabolic alterations are striking and include severe metabolic acidosis, hyperglycemia, glycosuria, ketonuria, and hyperkalemia [6,7,9]. The triad of seizures refractory to anticonvulsants, metabolic acidosis refractory to sodium bicarbonate therapy, and coma suggests INH toxicity.

Hepatotoxicity usually presents as elevated serum aspartate aminotransferase values within the first few months of therapy. Fatalities from INH-induced hepatitis during chemoprophylaxis are between 4.2 and 7.0 per 100,000 persons [24]. When peripheral neuropathy occurs, it is within 3 to 35 weeks of initiating the therapy [25]. Other chronic effects include dysarthria, irritability, seizures, dysphoria, and inability to concentrate [17]. Optic neuritis and optic atrophy have also been reported, but their occurrence is often associated with the administration of ethambutol as well.

Psychosis has been reported as early as 1957. The patients were usually taking therapeutic doses at the time of onset. Symptoms include irritability, disorientation, visual and auditory hallucinations, paranoid delusions, and suicidal ideation. INH-associated psychosis has been reported in patients on multiple and mono drug therapies, with and without a previous psychiatric history, and therapy with and without pyridoxine [26].

Pellagra is a syndrome of dermatitis, diarrhea, and dementia, which is potentially fatal. Its rare association with isoniazid was first reported in 1956 in a patient also taking prophylactic pyridoxine. It is thought that isoniazid and perhaps pyridoxine as well, competitively inhibit nicotinamide-adenine dinucleotide (NAD) and nicotinamide-adenine dinucleotide phosphate (NADP) production in genetically susceptible individuals. This causes a decreased ability to repair cellular damage in tissues with high cellular turnover rates, such as skin and gastrointestinal mucosa, resulting in photosensitivity and gastrointestinal cell damage [27].
DIAGNOSTIC EVALUATION

Initial laboratory evaluation should include serum electrolytes, blood urea nitrogen, creatinine, glucose, calcium, and magnesium levels. Laboratory workup for anion-gap metabolic acidosis (e.g., serum methanol, ethylene glycol, salicylate, and acetaminophen levels) should also be considered. Arterial blood gases, electrocardiogram, chest radiograph, head computed tomography, and lumbar puncture should be obtained as clinically indicated.

Qualitative INH identification in urine using reagent-impregnated paper strips or a point-of-care testing device sensitive to INH metabolites and quantitative serum INH identification are not widely available to be clinically useful in real time.

Acute INH intoxication should be considered in the differential diagnosis of any patient presenting with unexplained intractable seizure activity, metabolic acidosis, or coma \[6,10\]. See Table 116.1 for some conditions that may resemble INH toxicity and/or cause anion-gap metabolic acidosis.

Ingestion of rifampin–INH combination products may produce, in addition to the symptoms of INH poisoning, (a) a striking red-orange discoloration of the skin, urine, sclera, and mucus membranes; (b) periorbital or facial edema; (c) pruritus; and (d) nausea, vomiting, or diffuse abdominal tenderness [28]. Transient elevations in total bilirubin and alkaline phosphatase, indicating cholestasis, may also be noted.
MANAGEMENT

The initial management of a patient with acute INH overdose focuses on protection of airway, support of respiration, treatment of seizures, correction of metabolic acidosis, minimization of drug absorption, and in selected cases, enhancement of INH elimination.

Gastrointestinal decontamination, if performed, should consist of the administration of activated charcoal. Gastric lavage followed by activated charcoal should be considered in severely ill patients who have been intubated. Emesis is contraindicated because of the potential for rapid and unpredictable onset of seizures and coma.

Patients who have ingested a potentially toxic INH dose should be observed for at least 6 hours [6]; those who remain asymptomatic after gastrointestinal decontamination may be referred for psychiatric evaluation. All symptomatic patients should be admitted to an intensive care setting.

Seizures are often refractory to most conventional anticonvulsants [29]. Pyridoxine has dose-related effectiveness against convulsions and prevents lethality at doses from 75 to 300 mg per kg in canine models of INH toxicity [30]. In animal studies, when single-anticonvulsant regimens of pyridoxine, phenobarbital, pentobarbital, phenytoin, and diazepam were compared to the latter four anticonvulsants in combination with pyridoxine, pyridoxine was the only single agent that reduced the severity of convulsions and prevented death [29,30]. The combination of each of the other anticonvulsants with pyridoxine also prevented both convulsions and death. Therefore, pyridoxine, in conjunction with a benzodiazepine such as diazepam or lorazepam, is the preferred treatment for neurologic toxicity. Pyridoxine restores GABA production so that GABA agonists such as benzodiazepines or barbiturates can enhance GABA receptor activity. If pyridoxine is unavailable, diazepam appears to be the most effective single anticonvulsant, but its effectiveness may be limited and large doses may be required. Barbiturates are also effective, but may be more sedating than benzodiazepines.

Intravenous pyridoxine therapy should be administered at the first sign of neurologic toxicity in doses equal to the amount of INH ingested [6,7,31]. In patients actively convulsing, 1 g of pyridoxine should be administered for each gram of isoniazid ingested at a rate of 1 g per
minute. INH-overdosed patients treated with such pyridoxine doses exhibited no recurrent seizure activity, a decreased duration of coma, and prompt resolution of their metabolic acidosis [10]. If the amount of INH ingested is unknown, at least 5 g of pyridoxine should be administered [6,7]. In patients without seizures, the pyridoxine dose may be administered over 30 to 60 minutes. In those with seizure activity, it may be given as a bolus during 3 to 5 minutes. The pyridoxine dose should be repeated if seizures persist or recur. Intravenous diazepam or lorazepam should also be given in conjunction with pyridoxine [6,29]. As there may be inadequate intravenous stores of pyridoxine in treating facilities, oral high-dose pyridoxine may be tried in the same doses as intravenous pyridoxine [32]. To accomplish this, pyridoxine tablets may be crushed, mixed with fluid, and administered via nasogastric tube. Seizures refractory to pyridoxine and diazepam have been successfully treated with thiopental-induced coma. Reversal of prolonged INH-induced coma has been temporarily associated with pyridoxine therapy [33].

Treatment of metabolic acidosis should be guided by arterial blood gas and electrolyte measurements. In most cases, intravenous sodium bicarbonate will not correct acid–base abnormalities until seizure activity is terminated [10]. Bicarbonate should be considered if the serum pH is lower than 7.2 or if the acidosis does not rapidly resolve after seizure control.

Konigshausen et al. [34] reported two patients with apparent high-dose INH ingestions who presented with seizure and coma. One patient was treated with hemodialysis over 9 hours. His clearance rate was determined by arteriovenous differences as 76 mL per minute. The second patient was treated with pyridoxine and charcoal hemoperfusion. They reported that the initial CSF concentration fell from 25.6 to 4.1 μg per mL. The apparent half-life of 3.4 hours was within the reported normal elimination half-life for INH. The patient also underwent forced diuresis during that time. Both patients recovered fully. However, while hemodialysis and charcoal hemoperfusion can increase the clearance of INH and decrease its half-life by 50%, they have not been reported to remove significant quantities of INH (90 to 340 mg) [34–36].

Though exchange transfusion has been used in the treatment of isoniazid poisoning, there is no current application for its use [37]. The role of forced diuresis in the management of INH overdose is unproved. While large amounts of INH were recovered in the urine of some patients (43% to 58% of ingested doses), they are offset by those reporting minimal recovery (6 to 144 mg) [8,34,38]. Peritoneal dialysis is somewhat effective but inefficient [38]. One case using continuous venovenous hemodiafiltration (CVVHDF) reported a fourfold increase over endogenous clearance, but did not quantify the amount removed [39].

Considering the rapid elimination half-life of INH and the efficacy of
pyridoxine and benzodiazepine therapy, measures to enhance INH elimination are of limited use in the routine management of INH toxicity. However, patients with intractable acid–base disturbances, persistent seizures, liver or renal dysfunction, or coma may be considered candidates for hemodialysis or charcoal hemoperfusion [36]. Unless the patient has experienced significant anoxia as a result of coma or seizures, neurologic recovery may be expected within 24 to 48 hours.

Prevention of peripheral neuropathy during chronic INH therapy can be accomplished by the administration of pyridoxine, 15 to 50 mg per day, in high-risk patients. Peripheral neuropathy that develops during INH therapy is generally reversible on withdrawal of INH and treatment with high-dose pyridoxine (100 to 200 mg per day). However, the neuropathy may take months to a year or more to resolve, and in some cases, it may be permanent.

The management of INH-induced hepatotoxicity includes supportive care and cessation or reduction of INH administration. It is recommended that INH be discontinued in patients whose transaminase concentrations have risen to three times the upper limit of normal in the presence of jaundice or hepatitis symptoms or greater than five times the upper limit of normal if asymptomatic [18,40].

Psychosis usually responds to pyridoxine administration and patients may also benefit from antipsychotic medications such as risperidone or quetiapine [26].

The rare complication of pellagra responds to discontinuation of INH and institution of nicotinamide therapy [27].
REFERENCES

Lithium was introduced in the 19th century for the treatment of gout. Toxicity was rarely encountered because of low recommended doses. In the 1940s, lithium chloride was briefly marketed as a salt substitute, but was withdrawn after several cases of serious intoxication and death resulted from its use. In 1949, its antimanic properties were reported, and lithium has found increasingly wide psychiatric use since its approval by the U.S. Food and Drug Administration (FDA) in 1970 [1]. Lithium treatment in psychiatric diseases has been modified over five decades, but it remains a cornerstone “mood stabilizer” that is used worldwide [2].

Many studies have shown the benefits of lithium as a treatment for bipolar disorder, acute mania, and bipolar depression; however, recommendations concerning its clinical use vary among international guidelines. Lithium is recommended as monotherapy, as first-line treatment, or in combination with other antidepressive or antipsychotic agents based on different clinical scenarios and various guidelines [3].

Lithium induces neutrophilia (up to 1.5 to 2.0 times the reference leukocyte counts) by enhanced production of granulocyte colony-stimulating factor and stimulation of pluripotent stem cell production. Lithium has been prescribed for patients with various causes of neutropenia. Lithium has not been widely used in patients with thrombocytopenia despite evidence of megakaryocytopoiesis and thrombopoiesis demonstrated in a few studies [4,5].

Lithium is available in conventional tablets or capsules containing 150 mg, 300 mg, and 600 mg (4.06, 8.12, and 16.24 mmol, respectively) of lithium carbonate or in modified-release preparations containing 300 mg and 450 mg (8.12 and 12.18 mmol, respectively) of lithium carbonate. Liquid solutions of lithium citrate containing 8 mmol per 5 mL are also available. It is important to note that although lithium carbonate and lithium citrate are the commonly prescribed forms, other lithium salts (lithium acetate, lithium gluconate, lithium orotate, and lithium sulphate) are also available in some countries [6].
PHARMACOLOGY

Lithium is the lightest alkali metal (74 Da), occupying the same column in the periodic table as sodium and potassium, elements with which it shares some properties. Lithium forms a single-charged cation (Li+) that is associated with various salts. Lithium has no known normal physiologic role in the human body. The exact mechanism of its therapeutic and toxic effects remains poorly elucidated. Lithium is known to suppress inositol signaling, which may be the mechanism for mood stabilization. It inhibits glycogen synthase kinase-3, a component of diverse signaling pathways responsible for energy metabolism, neuroprotection, and neuroplasticity. Lithium decreases the release of norepinephrine and dopamine from terminal nerve endings and may temporarily increase the release of serotonin. Lithium affects ion transport and cell membrane potential by competing with sodium and potassium and possibly other cations. However, unlike sodium and potassium, lithium does not produce a large distribution gradient and, therefore, cannot maintain a significant membrane potential [6,7].

Lithium is readily absorbed from the gastrointestinal tract. The bioavailability of conventional tablets and capsules and the liquid solution is 95% to 100%; bioavailability is not affected by food. Normally, absorption is complete within 6 hours; peak levels are reached in 1 to 2 hours. Modified-release preparations are less predictably absorbed (60% to 90%), and peak levels may be lower than with the conventional form and may be delayed by more than 4 to 12 hours [6–8]. Overdose has resulted in delayed peak levels or secondary peak levels as long as 148 hours following ingestion [8].

Lithium initially occupies an apparent volume of distribution of 0.3 to 0.4 L per kg, but further distribution into various intracellular tissue compartments occurs over 6 to 10 hours, with a final volume of distribution of 0.7 to 1.0 L per kg. This explains why initial serum lithium levels may be very high, with few or no signs of toxicity. After a single dose, the equilibrium (postdistributional) serum lithium concentration can be expected to increase by 1.0 to 1.5 mmol per L for each 1.0 mmol of lithium per kilogram of body weight. Steady-state tissue levels are achieved after 3 to 4 days of therapy. Tissue distribution is uneven; whereas the cerebrospinal fluid lithium concentration is only 50% to 80% that of plasma, the bile concentration may be two times greater than that of plasma. Lithium is not bound to serum proteins. It freely crosses the placenta [6]. One animal study demonstrated that brain lithium accumulation is prominent in acute-on-chronically poisoned rats compared with acutely poisoned rats. Moreover, brain lithium distribution is increased in chronically poisoned rats compared with
Lithium is not metabolized. More than 95% of absorbed lithium is excreted by the kidneys, with 4% to 5% eliminated in sweat and 1% in the feces. It is also excreted in breast milk. Eighty percent of renally filtered lithium is reabsorbed in the proximal tubule (60%) and the thick ascending limb of the loop of Henle and collecting duct (20%) against a concentration gradient that does not distinguish lithium from sodium. Sodium depletion can result in as much as a 50% increase in lithium reabsorption. The usual renal clearance is 15 to 30 mL per minute, but it may be 10 to 15 mL per minute or less in the elderly and in patients with renal dysfunction or dehydration [6]. The lithium excretion rate may vary in different types of renal failure. One study demonstrated increased fractional excretion of lithium in patients with prerenal failure, but decreased fractional excretion in acute tubular necrosis renal failure [10]. The elimination half-life averages 16 to 30 hours; in patients with chronic intoxication, it may be as long as 58 hours [7,11].

Therapeutic levels are achieved by administration of 600 to 1,200 mg (16 to 32 mmol) of lithium carbonate per day in adults. Therapeutic serum lithium concentrations are usually considered to be 0.60 to 1.20 mmol per L; prophylaxis against recurrent manic-depressive illness may be achieved with levels of 0.75 to 1.00 mmol per L. Drug levels should be drawn at least 12 hours after the last dose to allow for complete tissue distribution. Onset of therapeutic effects usually requires 5 to 21 days after initiation of daily drug administration. Careful monitoring of lithium levels is essential because of its low toxic-to-therapeutic ratio or so-called narrow therapeutic index [2,3,12].

Lithium intoxication primarily involves the central nervous system (CNS) and kidneys, although a variety of other organ systems are also affected (Table 117.1). Lithium intoxication may follow an acute overdose, an increase in the daily therapeutic dose, or a decrease in lithium elimination by the kidneys. Most serious toxicity occurs in patients with chronic intoxication, especially in older patients and patients with renal insufficiency [11].

*Excludes one patient who also took temazepam in overdose.*

Acute ingestion of at least 40 mg per kg (1 mmol per kg) of lithium carbonate in a lithium-naive person would be required to produce a potentially toxic serum lithium level. The acute toxic dose in a patient already taking lithium (“acute-on-chronic” overdose) depends on the existing serum lithium level (“tissue soaking”). The dose required to produce chronic intoxication depends on the individual’s rate of renal lithium elimination.
CLINICAL MANIFESTATIONS

There are three clinical patterns of lithium intoxication: *acute* lithium poisoning in a lithium-naive individual who takes an acute overdose; *acute-on-chronic* lithium poisoning (a previously treated patient who takes an acute overdose); and *chronic* lithium poisoning in a previously treated patient who gradually accumulates lithium without taking an acute overdose [7]. Classification for severity of lithium intoxication may be based on serum lithium concentration: *mild* (1.5 to 2.5 mmol per L), *serious* (2.5 to 3.5 mmol per L), and *life-threatening* (>3.5 mmol per L). However, there does not appear to be a clear-cut relationship between serum concentrations and severity of toxicity, and decisions for treatment should be based on clinical parameters [13].

Symptoms and signs of mild lithium intoxication include nausea, vomiting, lethargy, fatigue, memory impairment, and fine tremor. Moderate signs and symptoms of toxicity include confusion, agitation, delirium, coarse tremor, hyperreflexia, hypertension, tachycardia, dysarthria, nystagmus, ataxia, muscle fasciculations, extrapyramidal syndromes, and choreoathetoid movements. Patients with severe toxicity may also exhibit bradycardia, complete heart block, coma, seizures, nonconvulsive status epilepticus (which may clinically resemble a nonictal encephalopathy), hyperthermia, neuroleptic malignant syndrome, serotonin syndrome, and hypotension [14]. Permanent sequelae include choreoathetosis, tardive dystonia, tremor, peripheral neuropathy, scanning speech, dysarthria, muscle rigidity, cognitive deficits, nystagmus, and ataxia [15].

Neurotoxic effects of lithium usually develop gradually and may become progressively severe over several days. Neurologic manifestations may worsen even as serum lithium levels are falling and may persist for days to weeks after cessation of the therapy, in part because of slow movement of lithium into and out of intracellular brain sites and possibly brain damage, such as demyelination caused by lithium. Lithium can cause persistent neurologic deficits longer than 2 months after cessation of lithium, also known as “Syndrome of Irreversible Lithium-Effectuated Neurotoxicity” or “SILENT.” The most common sequela of this syndrome appears to be persistent cerebellar dysfunction, but extrapyramidal, cognitive, and brainstem dysfunctions were also evident [15]. Reduced brain volume was demonstrated in one patient who suffered from SILENT [16]. Risk factors for SILENT include high serum lithium levels during acute intoxication, presence of fever, concomitant use of other drugs such as antipsychotics, tricyclic antidepressants, and anticonvulsive drugs. It is important to note that SILENT can occur in
patients with low or normal serum lithium levels [15].

Cardiovascular manifestations due to lithium intoxication are nonspecific and can be delayed owing to progressive equilibrium between intracellular and extracellular compartments. Abnormalities in the electrocardiogram (ECG) are often similar to those seen with hypokalemia and may result from displacement of intracellular potassium by lithium; U waves and flattened, biphasic, or inverted T waves can be seen with therapeutic doses and mild overdoses. Sinus and junctional bradycardia, sinoatrial and first-degree atrioventricular (AV) block, and QRS and QTc interval prolongation may be seen with severe intoxication [17]. Life-threatening dysrhythmias are rare but may result in death. Patients with complete heart block during lithium treatment have been reported [14,18]. This is more common in patients older than 65 years with baseline ECG abnormalities, conduction abnormalities, use of renal toxic medications, and concomitant use of AV nodal–blocking agents [18]. Lithium cardiotoxicity can mimic ischemia. A case of lithium intoxication with ECG findings of ST elevation and of a lithium-intoxicated patient who developed Takotsubo cardiomyopathy has been reported [19,20]. Pulse and blood pressure abnormalities may be seen in moderate or severe poisoning, but they are usually not pronounced. Hypotension is more often caused by dehydration, which can be a cause and a complication of lithium intoxication, rather than direct cardiotoxicity [17].

Effects on renal function in chronic lithium therapy include impaired urinary concentrating ability, nephrogenic diabetes insipidus (NDI), and a sodium-losing nephritis [2]. NDI is the most common renal side effect of lithium intoxication [21]. Clinically, this manifests as polyuria and polydipsia. Risk factors include lithium duration, dose, serum level, slow release form, and clinical nonresponse. These effects appear to be dose related and usually correct within several weeks of discontinuing the therapy [17]. Excessive water and sodium loss lead to increased proximal tubular reabsorption of lithium by transport mechanisms designed for sodium reabsorption. The accumulation of lithium may be enhanced by illnesses that result in decreased glomerular filtration rate, such as fever with sweating, gastroenteritis, and heart failure, or by diuretic drugs that enhance sodium and fluid loss. Rising lithium levels may further aggravate nephrotoxicity. A stable patient on a constant daily lithium dose with a therapeutic serum lithium concentration for years may suddenly develop life-threatening intoxication.

Metabolic abnormalities associated with lithium use include
hypercalcemia, hypermagnesemia, nonketotic hyperglycemia, transient diabetic ketoacidosis, and goiter. Hypothyroidism or hyperthyroidism due to lithium intoxication is rarely reported [2,17].

Lithium is classified as FDA pregnancy category D. It is teratogenic in rats, mice, and rabbits. Ebstein’s anomaly, hypothyroid, and “floppy-baby syndrome” have been reported in infants born to mothers on lithium therapy [2].

Several drugs may interact with lithium to alter its pharmacokinetics or directly enhance its toxicity. Diuretics may promote fluid and sodium depletion, leading to enhanced tubular lithium reabsorption. This effect appears to be much less apparent with furosemide than with thiazide diuretics. Aminophylline, urea, bicarbonate, and acetazolamide may decrease serum lithium levels by increasing the glomerular filtration rate. Nonsteroidal anti-inflammatory drugs, including the selective cyclooxygenase-2 inhibitor rofecoxib, may decrease the glomerular filtration rate and lithium elimination. Antipsychotic medications may have additive CNS depressant effects; in addition, lithium may enhance their dopamine-blocking and serotonergic effects and induce or aggravate rigidity and hyperthermia, possibly inducing neuroleptic malignant syndrome and serotonin syndrome [17]. Angiotensin-converting enzyme inhibitors have been reported to increase steady-state lithium concentrations by 36.1% and reduce lithium clearance by 25.5%, resulting in lithium toxicity [22].
DIAGNOSTIC EVALUATION

The history should include the type of lithium preparation ingested, the amount(s) and time(s) of ingestion, and the nature of the symptoms. It is important to differentiate patients with acute lithium overdose from those with chronic intoxication resulting from excessive daily doses or impaired renal elimination given that patients with chronic lithium intoxication can manifest greater toxicity despite lower serum lithium levels compared with acute overdose.

The physical examination should focus on the vital signs, neurologic function, and cardiovascular status. All patients should have an ECG and laboratory evaluation, including serum electrolytes, glucose, blood urea nitrogen, creatinine, and serum lithium level. Lithium levels should be obtained at least 12 hours after the last lithium dose and repeated at intervals of 4 to 6 hours after acute overdose until peak levels are observed. If the levels are elevated, they should be repeated until they are in the therapeutic range and the patient becomes asymptomatic [12].

Blood for thyroid function testing and calcium and magnesium levels may be warranted in some cases [2]. Electroencephalography (EEG) should be considered in patients who present with coma, altered or depressed mental status to rule out nonconvulsive status epilepticus. The EEG may demonstrate triphasic waves, commonly seen in metabolic encephalopathy, or bihemispheric slowing (4- to 5-Hz theta range) with bilateral periodic triphasic waves of 1- to 2-Hz frequency, which have also been found in a patient with Creutzfeldt–Jakob disease [23].

Patients with chronic lithium overdose are typically brought to medical attention by a family member or therapist because of gradual onset of neurologic symptoms. There is usually a recent history of excessive fluid loss caused by gastroenteritis, other infective illness, renal insufficiency, or the addition of new drugs such as diuretics and nonsteroidal anti-inflammatory agents [12].

After acute lithium overdose, the predominant initial symptoms are nausea, vomiting, abdominal pain, or diarrhea [2]. Patients do not usually have significant neurologic manifestations despite high serum lithium levels during the first 12 hours or more after ingestion because lithium is taken up slowly by the brain and other tissues [11]. Serum lithium concentrations as high as 10.6 mmol per L without significant toxicity have been reported after acute overdose [24]. However, toxicity may develop during the subsequent 24 to 48 hours, even as serum levels fall [15,17]. There does not appear to be any clinical variable that accurately predicts which patients will deteriorate. The use of cerebrospinal fluid levels to estimate brain levels more closely has been
advocated. However, cerebrospinal fluid levels do not reflect intracellular brain tissue levels or predict the level of coma [6,9].

Patients with acute-on-chronic lithium overdose have a clinical course similar to those following an acute overdose. However, a smaller total dose may produce severe intoxication, depending on the preoverdose serum lithium level.

Elevated blood urea nitrogen and creatinine reflect renal insufficiency and suggest that intoxication results from gradual accumulation of lithium rather than acute ingestion. Elevated creatinine may also be caused by cross-reactivity of the assay with creatinine from muscle destruction and should prompt the measurement of serum creatinine phosphokinase and urinalysis for myoglobinuria.

Patients with lithium-induced NDI usually have dilute urine with a low measured osmolality relative to serum. Hypernatremia can be observed. The diagnosis of NDI is confirmed by lack of urinary concentration in response to administered vasopressin [21].

Leukocytosis may be evident in patients on lithium therapy. It is a nonspecific finding and does not reflect severity of intoxication. A reduced or absent anion gap may occur with severe lithium carbonate intoxication, probably because the carbonate anion (but not the lithium cation) is measured and used in calculating the anion gap [25].

Plain abdomen imaging may or may not reveal radiopaque lithium tablets after acute ingestion. A negative radiograph should not be used to rule out an acute ingestion [26].

Differential diagnosis of patients with lithium poisoning includes hypoxia, hypoglycemia, hypothermia or hyperthermia, electrolyte disturbances, CNS infection, head trauma, and intracranial bleeding. In a patient with hyperthermia and rigidity who is also taking antipsychotic medications, neuroleptic malignant syndrome and serotonin syndrome should be considered. Other drug intoxications should be considered, especially if CNS symptoms appear shortly after an acute overdose.
MANAGEMENT

Initial management of patients with altered mental status should include assessment and stabilization of the airway; administration of oxygen and assisted ventilation, if needed; vascular access and continuous ECG monitoring; and administration of drugs (e.g., dextrose, naloxone, and thiamine) if appropriate. Benzodiazepines or barbiturates should be administered to patients with seizures. The EEG should be used to confirm the resolution of seizure activity in patients with nonconvulsive status epilepticus. If hyperthermia is present, cooling measures should be instituted, including evaporative cooling, tepid sponging, and fanning. Neuromuscular paralysis and endotracheal intubation, a reliable approach to rapidly lower body temperature, can be considered as needed. Hypovolemia, if present, should be treated with intravenous crystalloids. Cardiac dysrhythmias do not usually require treatment, but should respond to the current recommended pharmacologic treatment of dysrhythmias.

Gastrointestinal tract decontamination should be considered after acute ingestion to prevent continued absorption of lithium. Ipecac-induced emesis is not recommended. Gastric lavage may be of benefit in selected clinical situations (e.g., symptomatic patient following a massive overdose) [27]. Activated charcoal does not effectively bind lithium and should be given only if coingestion of another drug is suspected [28]. Whole-bowel irrigation (see Chapter 97) has been recommended for large ingestions, especially if they involve modified-release tablets [29]. If a tablet mass or concretion is suspected because of sustained high levels after 2 to 3 days, contrast imaging studies, ultrasound, or gastroduodenal endoscopy and endoscopic removal should be considered [30]. Preliminary evidence in animals and human volunteers suggests that the cation exchange resin sodium polystyrene sulfonate (Kayexalate) binds lithium and may enhance its elimination [31–33]. One case report describes its use in a patient with acute-on-chronic lithium overdose. Treatment emergent adverse events include constipation and mild hypokalemia. The clinical effectiveness of sodium polystyrene sulfonate treatment in lithium overdose remains to be determined.

Observation in asymptomatic patients following an acute or acute-on-chronic overdose of lithium in conventional formulation should be for a minimum of 6 hours, and observation for a minimum of 24 hours following an overdose of lithium in modified-release formulation [6–8]. Serial lithium levels should be obtained to confirm lack of significant absorption. Patients with mild overdoses can often be monitored and treated in the emergency department. Symptomatic patients, patients
with a massive acute ingestion, and those whose levels continue to rise beyond 6 hours after ingestion should be admitted to an intensive care setting.

Delayed clinical manifestations and peak serum lithium concentrations may occur in patients who overdose on modified-release formulations of lithium. Serial serum lithium concentrations should be obtained (e.g., every 4 to 6 hours) until serum lithium concentrations have decreased to the therapeutic range.

Lithium-induced NDI does not respond to vasopressin, but it has been reported to improve with hydrochlorothiazide, amiloride, carbamazepine, and indomethacin [17]. However, the gradual onset and the duration required of hydrochlorothiazide, carbamazepine, and amiloride therapy would limit their clinical usefulness. One case report suggests indomethacin may be acutely effective in treating lithium-induced NDI [34].

Intravenous fluid therapy is effective in restoring glomerular filtration rate and maintaining renal elimination of lithium in most patients with mild or moderate intoxication. A crystalloid solution (half-normal or normal saline) aiming for urine output of 1 to 3 mL/kg/h should be administered after an initial saline bolus (10 to 20 mL per kg), depending on the degree of dehydration. Serum electrolytes should be followed closely because hypernatremia may occur.

A crude estimate of renal lithium clearance can be calculated from simultaneous urine and serum lithium levels and urine flow rate: Renal lithium clearance = urine flow rate (mL per minute) × urine lithium (mmol per L)/serum lithium (mmol per L). Normal lithium clearance is 15 to 30 mL per minute. If the clearance is below normal in a patient without underlying cardiac or renal dysfunction, the rate of fluid administration should be increased because this suggests low renal perfusion secondary to dehydration. In human studies, water loading, furosemide, thiazide, ethacrynic acid, ammonium chloride, and spironolactone did not increase lithium clearance.

Hemodialysis is the most efficient method for removing lithium, achieving clearance rates of up to 170 to 180 mL per minute [7,35,36]. However, lithium is only slowly removed from intracellular tissue compartments, especially the brain, and rebound increases of serum lithium levels often occur within several hours after dialysis. Hemodialysis should be repeated frequently until the serum level drawn 6 to 8 hours after the last dialysis is 1 mmol per L or less [7,12,36]. However, despite repeated dialyses, patients with significant neurologic toxicity do not promptly improve. Recovery, if it occurs, may be protracted.

The indications for hemodialysis are not well established, and hence recommendations for management of lithium poisoning vary widely, as
demonstrated in a survey of 163 health care professionals from 33 countries [37]. It is generally agreed that patients with severe clinical toxicity and those with renal dysfunction should undergo dialysis. Asymptomatic patients or those with mild-to-moderate intoxication who are otherwise healthy may be managed with intravenous fluids as long as they remain clinically stable or are improving with satisfactory lithium clearance (>15 to 20 mL per minute). Renal replacement therapy (e.g., venovenous or arteriovenous hemodiafiltration) has been reported to successfully remove lithium without the need for hemodialysis [38]. In one case, 14 hours of continuous arteriovenous hemodiafiltration was estimated to achieve lithium elimination equivalent to 5.75 hours of hemodialysis [39]. In another case report, clearances of up to 38 mL per minute were achieved with continuous venovenous hemodiafiltration [40]. However, in the acute setting, hemodialysis is most effective for quickly reducing the serum lithium concentration, and it can be followed by continuous renal replacement therapy to maintain a slow but continuous removal of lithium, thus mitigating a rebound in the central compartment lithium concentration.

A systematic review and consensus recommendations were published in 2015 by the Extracorporeal Treatments in Poisoning (EXTRIP) Workgroup, an international panel of reviewers from a broad range of medical specialties and representing diverse professional societies. The systematic review indicated there is a very low quality of evidence for all recommendations, because most publications were case reports. The panel’s recommendation for extracorporeal treatment based on history taking, physical examination, ECG findings, and serum lithium levels were based largely on opinion [7]. Recommendations by the EXTRIP Workgroup are summarized in Figure 117.1.
FIGURE 117.1 Extracorporeal Treatment (ECTR) for lithium poisoning; Recommendation from the Extracorporeal Treatments in Poisoning (EXTRIP) Workgroup (2015). Impaired kidney function defined as (1) stage 3B, 4 or 5 CKD (i.e., eGFR <45 mL/min per 1.73 m²; (2) Kidney Disease Improving Global Outcomes stage 2 or 3 AKI; (3) If no baseline creatinine, Serum Cr $2$ mg/dL (176 μmol/L) in adults and $1.5$ mg/dL (132 μmol/L) in elderly/low-muscle mass patients; and (4) If no baseline creatinine, Serum Cr > $2$ times the upper limit of normal for age and sex in children, the presence of oligo/anuria should raise awareness of impaired kidney function. 1D: Strong recommendation, very low evidence, 2D: Weak recommendation, very low evidence.

7. Teece S, Crawford I: Best evidence topic report: no clinical evidence for

The methylxanthines most commonly used in the clinical setting are theophylline and its ethylenediamine salt, aminophylline. Until recently, theophylline was used exclusively as a bronchodilator for the management of reversible obstructive pulmonary diseases and as a respiratory stimulant for the treatment of apnea of prematurity in neonates. During the 1980s, its use fell dramatically as more effective therapies for recurrent bronchospasm became available [1]. However, there has been renewed interest in theophylline as the scope of its pharmacologic benefits broadens. Potential uses for theophylline now include preconditioning of cardiac ischemia [2], treatment of bradycardia [3], amelioration of perinatal asphyxia [4], and protection from contrast-induced nephropathy [5]. Recent clinical trials of theophylline for asthma have demonstrated substantial benefit, restoring interest in the drug for this indication [6,7]. Despite its renewed popularity, theophylline, with its potent pharmacologic actions, variable metabolic disposition in humans, and narrow therapeutic-to-toxic ratio, is a common cause of intoxication [1,8].

Caffeine and theobromine are other widely used methylxanthines. Caffeine is found in beverages such as coffee and tea, energy drinks (e.g., sodas or water) or dietary energy supplements (e.g., guarana or kola), energy foods such as mints and gum, and pharmaceutical preparations (e.g., antisleep drugs). Although severe toxicity from caffeine ingestion is uncommon, case reports of serious poisoning in children and adults are well documented [9]. Because caffeine and other xanthine derivatives are structurally similar to theophylline, signs and symptoms of toxicity resemble those seen in theophylline intoxication, and the approach to management should be similar.

Three clinical circumstances account for most cases of theophylline poisoning: unintentional ingestions by children, intentional ingestions (suicide attempts) by adolescents or adults, and medication errors (miscalculation of dose, change in frequency of administration, lack of serum drug level monitoring, or an unrecognized drug–drug or drug–
disease interaction) [1,10,11]. Most cases of theophylline intoxication result from chronic, unintentional overmedication.

**PHARMACOLOGY**

Theophylline is available commercially as a liquid, tablet, sustained-release capsule, or solution for intravenous administration. Overdose of sustained-release theophylline can lead to a marked delay in complete absorption, with peak serum theophylline concentrations occurring as long as 15 to 24 hours after ingestion [12]. Therapeutic serum theophylline concentrations range from 10 to 20 μg per mL.

A loading dose of 5 to 6 mg per kg of intravenous aminophylline should produce a serum theophylline level of 10 μg per mL in patients not currently taking theophylline. Maintenance dosages vary with age and underlying conditions (Table 118.1). For patients taking theophylline regularly, a loading dose increases the steady-state serum theophylline level. Typically, administration of 1 mg per kg of theophylline raises the serum drug concentration by 2 μg per mL. This relationship can also be used to predict the theophylline concentration after an overdose; the maximum possible drug concentration (in μg per mL) should be no more than twice the ingested or administered dose (in mg per kg).

Theophylline has a volume of distribution of 0.4 L per kg and is 40% to 65% bound to plasma proteins [13]. Its metabolism is almost exclusively by hepatic cytochrome P450 system; it is oxidized or demethylate in the liver by at least two isoenzymes (CYP1A2 and CYP3A4) [13]. Less than 15% of the drug is excreted unchanged in urine. At therapeutic doses, hepatic metabolism generally occurs by first-order elimination kinetics [14]. The drug exhibits saturable (Michaelis–Menten) kinetics in overdose leading to prolonged, unpredictable elimination rates. The elimination half-life of theophylline also varies widely with age: typical half-lives are 20 to 30 hours in premature infants, 4 to 7 hours in newborns, 3 to 4 hours in children 6 months to 18 years of age, and 8 to 9 hours in adults [13,14]. Many xenobiotics, chemicals, and medical conditions affect the steady-state serum concentration and elimination half-life of theophylline (Table 118.2). The xenobiotics that inhibit theophylline clearance are those that inhibit CYP1A2 and CYP3A4, including erythromycin, clarithromycin, ciprofloxacin, and cimetidine [13,15]. Xenobiotics that increase theophylline clearance include barbiturates, carbamazepine, and the polyaromatic hydrocarbons of cigarette smoke (including passive smoke inhalation) [16]. Enzyme induction by these xenobiotics can be temporary; in patients who smoke quit abruptly, theophylline clearance can fall to normal within days, leading to inadvertent theophylline intoxication unless dose is adjusted accordingly. Several disease states are also associated with a reduction in theophylline clearance, including heart failure and liver disease [13]. Both hyperthyroidism and cystic fibrosis are associated with increased elimination of theophylline [17].

Theophylline has a variety of physiologic effects at therapeutic doses (Table 118.3). These effects include smooth muscle relaxation, mild central nervous system (CNS) excitation, and diuresis. Intoxication is associated with an array of other metabolic and clinical consequences. Although the effects of theophylline have been well characterized, their pharmacologic and pathophysiologic mechanisms remain poorly understood. Three primary cellular mechanisms of theophylline action have been theorized: inhibition of cyclic guanosine monophosphate or cyclic adenosine monophosphate (cAMP) activity, adenosine receptor antagonism, and adrenergic hyperstimulation (particularly at the β-receptor) secondary to elevated levels of circulating plasma catecholamines [18,19]. Inhibition of calcium translocation and leukotriene production have also been postulated as additional mechanisms.

Disturbances in depolarization (e.g., tremor)

The physiologic changes seen with therapeutic doses of theophylline, including tachycardia, diuresis, bronchodilation, and CNS excitation, were thought to result from theophylline’s inhibition of phosphodiesterase, the intracellular enzyme that inactivates cAMP, an important “second messenger” [20]. Such enzyme inhibition would lead to elevated intracellular cAMP concentrations, affecting a broad range of physiologic responses. However, this theory has been brought into question; in vitro data suggest phosphodiesterase inhibition does not
occur at therapeutic serum concentrations of theophylline and that increased cAMP activity is not a major mechanism of its therapeutic effects [21]. Whether the increased theophylline concentrations seen in the intoxicated patient are sufficient to inhibit phosphodiesterase activity is unclear.

Investigation has also been directed at the role of adenosine receptor antagonism as a mechanism of theophylline action. Adenosine is a nucleoside that promotes smooth muscle constriction, slows cardiac conduction, and acts as an endogenous anticonvulsant. With the structure of theophylline being similar to that of adenosine and with the drug having opposite physiologic actions, theophylline may be a simple competitive antagonist at bronchial and vascular smooth muscle, cardiac, and CNS sites. However, adenosine antagonism alone does not provide a complete explanation for theophylline’s pharmacologic effects [22].

Additional data suggest that many of theophylline’s actions can be accounted for by its stimulation of plasma catecholamine release [17]. Plasma concentrations of epinephrine, norepinephrine, and dopamine all rise significantly after theophylline administration. With therapeutic doses, plasma catecholamine activity typically increases four- to sixfold. After theophylline intoxication, plasma catecholamine activity may rise to 30-fold [18,19]. Increased plasma catecholamines provide a ready explanation for many of the effects of theophylline seen after therapeutic doses and potentially mediate many of the effects of theophylline intoxication. In all probability, the combined effects of adenosine receptor antagonism and catecholamine release are responsible for most features of theophylline intoxication.

Plasma catecholamines, particularly epinephrine, are capable of inducing hypokalemia, hyperglycemia, and metabolic acidosis. Epinephrine-induced hypokalemia appears to result from $\beta_2$-adrenergic receptor–linked stimulation of Na$^+$/K$^+$ adenosine triphosphatase. This leads to increased intracellular transport of potassium with preservation of total body potassium content [23]. Consistent with the theories of plasma catecholamine activity is the observation that theophylline-induced hypokalemia can be inhibited by pretreatment with propranolol or reversed by propranolol administration [24].

The CNS effects of theophylline intoxication include respiratory stimulation, vomiting, and seizures. These may result from disturbances in CNS cyclic guanosine monophosphate activity, adenosine antagonism, or adrenergic excess. Changes in neuronal transmembrane potentials by any of these mechanisms would lower excitation thresholds. In addition,
there are theories that theophylline inhibits CNS γ-aminobutyric acid receptor activity and stimulates N-methyl-D-aspartate and other excitatory neurotransmitter production. Theophylline administration has been associated with an abnormal electroencephalogram pattern in 34% of children and 12% of adults [25]. Cerebral vascular effects are also significant with theophylline and other methylxanthines because they are potent cerebral vasoconstrictors. This is the presumed mechanism of the efficacy of caffeine in the treatment of migraine headache. However, decreases in cerebral blood flow can be extreme, particularly during inhalational anesthetic administration [26].
CLINICAL TOXICITY

Manifestations of theophylline intoxication can be classified into five categories: cardiac, CNS, gastrointestinal, musculoskeletal, and metabolic [1,8]. The cardiovascular effects of theophylline intoxication consist of rhythm and vascular disturbances. The hallmark (and first sign) of theophylline poisoning is sinus tachycardia, which occurs in more than 95% of cases. With more severe intoxication, unstable supraventricular tachydysrhythmias and ventricular dysrhythmias may occur. A common cause of death with severe theophylline intoxication is intractable ventricular dysrhythmias.

Blood pressure disturbances are also common. At lower ranges of intoxication, a mildly elevated blood pressure may be present, although severe hypertension is unusual in isolated theophylline poisoning. In severe cases of theophylline poisoning, hypotension with a widened pulse pressure is seen in the face of an increased cardiac index. Hypotension is caused by a marked fall in systemic vascular resistance.

The CNS effects of theophylline poisoning become prominent for those with severe overdose. The stimulatory actions of theophylline first produce hyperventilation with mild respiratory alkalosis. Significantly intoxicated patients develop agitation and anxiety. Vomiting, which can be severe, results partly from stimulation of the vomiting center of the medullary chemoreceptor trigger zone.

The most severe CNS manifestation of theophylline intoxication is seizures; these are a poor prognostic sign. Theophylline-induced seizures are typically tonic–clonic in nature and may be focal; they may be single, but are commonly multiple and typically resistant to conventional anticonvulsants. Seizures after theophylline intoxication are associated with a high frequency of adverse neurologic outcomes and a mortality that approaches 50% among elderly patients [27].

The gastrointestinal effects of theophylline poisoning consist of vomiting, diarrhea, and hematemesis. Vomiting results in part from hypersecretion of gastric acid and the enzymes gastrin and pepsin [28]. These acids and digestive enzymes are gastric irritants that can produce mucosal hemorrhage with hematemesis. Finally, theophylline is a potent relaxer of lower esophageal sphincter resting tone; this action facilitates the reflux of gastric contents.

Skeletal muscle tremor is a common feature of theophylline poisoning. These tremors are coarse; myclonic jerks may also be present. Muscular hypertonicity also appears to be linked to theophylline’s actions as a $\beta_2$-adrenoreceptor; this is evidenced by a similar syndrome occurring after excess administration of potent $\beta_2$-agonists (e.g., terbutaline).
A number of metabolic disturbances accompany theophylline intoxication: metabolic acidosis, hypokalemia, hyperglycemia, hypophosphatemia, hypomagnesemia, and hypercalcemia \([29,30]\). Metabolic acidosis may appear late and is typically modest; acidemia may not occur because of a superimposed respiratory alkalosis. Hypokalemia and hyperglycemia correlate strongly with the degree of intoxication after acute theophylline poisoning \([31]\). However, there are no obvious clinical consequences of hypokalemia. Hypercalcemia and hypophosphatemia are common, but not invariable, disturbances. Their cause is unclear, although theophylline (and epinephrine) has been shown to increase concentrations of parathyroid hormone, and correction of theophylline-induced hypercalcemia has been reported after propranolol administration \([32]\).

Several studies have suggested that the metabolic and clinical consequences of theophylline intoxication vary, depending on whether the poisoning occurs through a single ingestion (or single intravenous overdose), chronic overmedication, or acute-on-therapeutic intoxication, in which the patient has maintained serum theophylline concentrations in the therapeutic range but then received a single toxic dose \([11]\). With \textit{acute theophylline intoxication}, the patient ingests a single toxic dose of theophylline or inadvertently receives a toxic dose of intravenous aminophylline. The clinical course of acute theophylline intoxication strongly correlates with serum theophylline concentration. Serum theophylline concentrations of 20 to 40 \(\mu\)g per mL are associated with nausea, vomiting, and tachycardia. When theophylline concentrations are 40 to 70 \(\mu\)g per mL, premature ventricular contractions, agitation, and tremor appear. At theophylline concentrations greater than 80 \(\mu\)g per mL, life-threatening events, including severe cardiac dysrhythmias and intractable seizures, may occur \((\text{Table 118.4})\) \([33]\). Hypokalemia can be profound after acute intoxication, with serum potassium concentrations falling to as low as 2.1 mEq per L. Serum glucose can be as high as 300 to 350 mg per dL.

\end{tabular}
\caption{Signs and Symptoms Associated with Acute Theophylline Toxicity}
\end{table}
In chronic theophylline overmedication, the patient ingests theophylline for at least 24 hours in doses or under conditions that exceed theophylline clearance. The result is a relatively slow rise in body “theophylline burden” to toxic concentrations. Victims of chronic overmedication are more likely to be neonates or elderly patients who have underlying cardiac disease or are taking/receiving medications that inhibit theophylline metabolism. These factors contribute to greater morbidity and mortality after chronic theophylline overmedication [1]. Signs of severe intoxication may occur with steady-state serum theophylline concentrations as low as 20 to 30 μg per mL. Seizures have occurred in patients with concentrations as low as 17 μg per mL. Patients with chronic theophylline overmedication are also less likely to have hypokalemia and hyperglycemia. The most striking feature of chronic theophylline overmedication is that there is no significant correlation between serum theophylline concentration and the appearance of life-threatening events [1,11,34]. Seizures and dysrhythmias may appear with serum theophylline concentrations in the therapeutic or mildly toxic range [11,34]. As a result, serum theophylline concentration should not be used to predict the appearance of these events.

Patients who are chronically receiving theophylline in appropriate doses and then take or receive an acute overdose of theophylline develop acute-on-therapeutic theophylline intoxication. In these patients, clinical and metabolic consequences have features that are intermediate between those found with acute intoxication and chronic overmedication. Clinical manifestations are somewhat predicted by peak serum theophylline concentration, with life-threatening events usually not appearing until serum theophylline concentrations exceed 60 μg per mL. Metabolic disturbances are not as severe and have little or no correlation with serum theophylline concentration [1,10,11].
Patient age appears to be a significant risk factor for the development of life-threatening events after theophylline intoxication for those at extremes of age (i.e., neonates and elderly patients) [1]. For example, after chronic overmedication, patients older than 75 years have an almost 10-fold greater risk of a life-threatening event than do adolescents with comparable serum theophylline concentration [1]. There is evidence that for patients with chronic theophylline intoxication, age is a better predictor of major toxicity than serum theophylline concentration. Potential explanations for this observation include the differing pharmacokinetics found at extremes of age or the higher prevalence of significant underlying multisystem disease and use of multiple drugs in these patients.
DIAGNOSTIC EVALUATION

Essential laboratory studies to obtain in the patient with theophylline intoxication include serum theophylline concentration, serum electrolytes, blood urea nitrogen, creatinine, glucose, calcium, magnesium, phosphorus, liver function panel, and creatinine phosphokinase. Urine should be frequently evaluated for evidence of myoglobinuria. An electrocardiogram should be obtained; all patients with theophylline intoxication should be placed on continuous electrocardiogram monitoring. Arterial blood gas and complete blood cell count should be obtained as clinically indicated.

Sequential serum theophylline concentrations should be obtained every 1 to 2 hours until a plateau and subsequent substantive decline have been documented because delayed peaks in serum theophylline concentration may occur after an overdose. All abnormal laboratory studies should be serially monitored until all values have returned to baseline.
MANAGEMENT

The management of theophylline intoxication consists of stabilization, decreasing absorption, and enhancing elimination. After acute ingestion, decreasing absorption is a primary concern. Treatment of chronic intoxication or intoxication after intravenous administration of theophylline generally focuses more on enhancing elimination.

Airway protection is paramount, and the threshold for tracheal intubation in the patient with seizures or other alterations in consciousness should be low. Assisted ventilation may be necessary if there is coingestion of a CNS depressant or if medications that depress respiratory drive, such as diazepam for seizures, are required for management.

If hypotension does not respond to an initial intravenous fluid bolus, propranolol may have a positive effect on blood pressure stabilization. If a vasopressor is also required, α-adrenergic agents such as phenylephrine or norepinephrine may be more efficacious; dopamine, which has some vasodilating properties at low doses, may be relatively ineffective.

Although no controlled clinical studies are available, there have been reports of success in treating tachydysrhythmias, particularly supraventricular tachycardias, with β-adrenergic antagonists, such as propranolol. Propranolol counters tachycardia, restores coronary blood flow, and interrupts the reentry phenomena that often underlie theophylline-induced dysrhythmias [18]. A potential hazard of propranolol administration is drug-induced bronchospasm; therefore, it should be used cautiously, if at all, in patients with significant reactive airways disease. Esmolol, an ultrashort-acting β₁-selective antagonist, has also been shown to be effective for select theophylline-induced tachydysrhythmias [35].

The antidysrhythmic agent adenosine has become the treatment of choice for supraventricular tachycardias and may be an important therapeutic addition in the management of theophylline-induced tachyarrhythmias. Having a significant effect on atrioventricular node conduction, adenosine can promptly reverse supraventricular tachycardias. Moreover, because of the evidence that adenosine and theophylline compete for the same receptor, adenosine may be a specific antidote for theophylline-induced supraventricular tachycardia. However, published clinical data in this regard are limited [36,37]. Amiodarone or lidocaine is the recommended treatment of ventricular irritability associated with hemodynamic compromise.

Seizures should be treated aggressively. High-dose benzodiazepine may be necessary for seizure termination. Phenytoin may be ineffective for
theophylline-induced seizures [38], and in animal studies, it appears to contribute to theophylline-induced seizures. If seizures become prolonged, a rapid-acting barbiturate, such as thiopental or pentobarbital, may be necessary. Neuromuscular blockade and general anesthesia should be considered for seizures that are unresponsive to these modalities, because significant morbidity may result from the rhabdomyolysis, hyperthermia, and acidosis of status epilepticus. There is some evidence that propranolol may help prevent or control theophylline-induced seizures [39].

Vomiting can be treated with the H$_2$-antagonist ranitidine, which reduces gastric acid hypersecretion [40]. Cimetidine administration is relatively contraindicated in theophylline poisoning because it inhibits theophylline metabolism. The dose of ranitidine is 50 to 100 mg per kg given intravenously for adults and 0.1 to 0.5 mg per kg for children. Doses can be repeated every 6 to 8 hours. Metoclopramide also is an effective antiemetic that stimulates upper gastrointestinal motility and increases lower esophageal tone, without affecting theophylline clearance. The initial dose of metoclopramide is 0.5 to 1.0 mg per kg given intravenously for adults or 0.1 mg per kg for children (maximum, 1.0 mg per kg) and is associated with dystonic reactions. Ondansetron is an alternative antiemetic, offering the advantage of effective antiemesis with no alterations in mental status and no risk of dystonic reaction. The phenothiazine antiemetics prochlorperazine and promethazine can lower seizure threshold and should not be administered.

Treatment of metabolic acidosis is aimed at maintaining a normal serum pH. For hypokalemia, it is important to emphasize that because hypokalemia’s origin is predominantly the intracellular shift of potassium with minimal losses of total body potassium content through urine or vomitus, reversal of hypokalemia is best accomplished by lowering the theophylline concentration. Aggressive replacement of potassium may result in “overshoot” hyperkalemia [41]. Intravenous infusions of potassium chloride or potassium phosphate at 40 mEq per L in a saline solution should be adequate; intravenous boluses are usually not indicated. Hypophosphatemia, hypomagnesemia, hypercalcemia, and hyperglycemia rarely require correction.

Because vomiting is such a prominent feature of theophylline intoxication, there is rarely a need to perform gastric emptying. However, activated charcoal (see Chapter 97) is highly effective in reducing the absorption of theophylline and should be administered to all patients with recent ingestions. Whole-bowel irrigation (see Chapter 97) may be
effective, particularly for sustained-release formulations, but its role in the treatment of theophylline intoxication remains undefined.

The repeated administration of activated charcoal (multiple-dose activated charcoal [MDAC]; see Chapter 97) is a valuable therapeutic measure for enhancing theophylline elimination [42,43]. Moreover, because MDAC acts through the principle of “gastrointestinal dialysis,” it is effective even if theophylline intoxication occurs after intravenous administration of aminophylline. MDAC is potentially as effective as hemodialysis in accelerating theophylline clearance [44]. However, it is not a substitute for hemodialysis in situations where rapid reduction in body theophylline burden is essential. All patients with significant theophylline intoxication should receive MDAC until the theophylline level is less than 15 μg per mL. Typical dosing is 1 g per kg charcoal every 4 hours (maximum, 50 g per dose). An effective alternative is 20 g every 2 hours [43]. Another alternative to bolus serial charcoal is administration via continuous nasogastric infusion at a rate of 0.25 to 0.50 g/kg/h.

Repeated vomiting, present in up to 80% of patients with theophylline intoxication [45], may delay or prevent successful MDAC administration. Aggressive antiemetic therapy is usually necessary.

In severely intoxicated patients or patients with moderate toxicity who are unable to tolerate MDAC, rapid removal of theophylline is essential. This is best accomplished by hemodialysis or hemoperfusion. If the need for extracorporeal drug removal is anticipated, a nephrologist should be involved early in management. Because of the time and personnel required to initiate extracorporeal drug removal, early notification can expedite the process once the decision has been made. Morbidity and mortality may be significantly lower if these procedures are undertaken before the onset of life-threatening disturbances. Indications for extracorporeal drug removal include hemodynamic instability or repeated seizures (regardless of serum theophylline concentration) and acute intoxication with a serum theophylline concentration greater than 80 μg per mL. Extracorporeal measures should be considered in patients younger than 6 months or older than 60 years with chronic intoxication and a theophylline concentration greater than 30 μg per mL (Table 118.5).

Charcoal hemoperfusion has traditionally been considered the extracorporeal drug-removal method of choice for theophylline intoxication [46]. It reduces the elimination half-life of theophylline to as low as 0.7 to 2.1 hours [44], increasing clearance four- to sixfold [46]. However, hemoperfusion has significant risks, including hypotension, thrombocytopenia, red cell destruction, bleeding diathesis, and hypocalcemia. Also, there are few medical centers with the equipment and personnel needed to perform this procedure. The combination of scarce access to the procedure, increasing efficiency of hemodialysis, and the comparable efficacy of the two procedures has made hemodialysis the preferred procedure for treatment of severe theophylline intoxication [47].

Hemodialysis has many advantages over hemoperfusion. First, it is a technique that is widely available and relatively simple to perform. The need for administration of blood products is considerably less with hemodialysis. Dialysis can also increase theophylline clearance substantially, depending on the blood flow rates achieved by the device. Also, hemodialysis does not require the same degree of anticoagulation required by hemoperfusion, which lowers the risk of bleeding diathesis. Finally, the overall rate of complications is lower for hemodialysis than for hemoperfusion.

Peritoneal dialysis is an ineffective mode of drug removal in theophylline intoxication and is not recommended. Exchange transfusion, formerly thought to have no role in theophylline poisoning, has been used successfully in neonates with severe intoxication [48]. Other extracorporeal drug-removal methods, such as hemofiltration and plasmapheresis, have not been sufficiently evaluated, although there are case reports that these procedures have therapeutic value [49]. Hemofiltration, because it is a slow, passive, cardiac output–dependent technique, is unlikely to effect the rapid removal of theophylline that is necessary in severe intoxications.
CAFFEINE

Caffeine is a component of the three most popular beverages in the world: coffee, tea, and carbonated soft drinks. It is also used therapeutically as an antishleep aid and in many headache medications. Having a wide margin of safety and a relatively short elimination half-life—3 hours in adults, but 1 to 6 days in neonates—caffeine can be ingested daily in amounts as high as 1 g [50]. However, daily doses in this range are associated with adverse events such as anxiety, jitteriness, and tachycardia. The U.S. Food and Drug Administration considers caffeine in cola-type beverages to be generally regarded as safe [51].

The pharmacokinetic profile of caffeine resembles theophylline, with an important exception: whereas metabolism of theophylline (1,3-dimethylxanthine) produces inactive metabolites, caffeine (1,3,7-trimethylxanthine) undergoes 7-demethylation to form theophylline. Therefore, caffeine ingestion is invariably associated with measurable serum theophylline concentrations. After caffeine intoxication, serum theophylline concentration is a useful measure of toxicity. Many of the clinical manifestations of caffeine intoxication may in fact result from the effects of theophylline at its susceptible end organs.

The single ingestion of more than 1.5 g of caffeine (30 to 50 mg per kg in children) can produce serious adverse effects with the same manifestations found in acute theophylline intoxication [52]. Ingestions of more than 100 to 200 mg per kg are potentially lethal [50]. The five major disturbances occurring after caffeine intoxication are gastrointestinal, neurologic, metabolic, cardiac, and musculoskeletal [9]. Nausea and vomiting, with occasional hematemesis, predominate. CNS excitation may be manifested by anxiety, agitation, and seizures in severe cases. The same hypokalemia, hyperglycemia, and metabolic acidosis that appear after severe acute theophylline intoxication occur with caffeine poisoning. The most common cause of death after caffeine intoxication is intractable cardiac dysrhythmias [53]; severe acute overdoses have led to myocardial infarction. Musculoskeletal effects can be prominent with caffeine intoxication; one feature is the appearance of severe rhabdomyolysis. Life-threatening events after acute caffeine intoxication are associated with serum concentrations of more than 100 to 150 μg per mL. However, seizures after caffeine intoxication have occurred at serum concentrations as low as 50 μg per mL. Death has been reported with serum concentrations as low as 80 μg per mL. However, serum caffeine concentrations as high as 385 μg per mL have been associated with survival [54].
In recent years, the growing popularity of “energy” drinks and foods containing caffeine, taurine, and guarana has led to increased concerns regarding caffeine toxicity. The amount of caffeine contained in these drinks and foods is highly variable, and the reported amounts often do not take into account guarana and other additives. Rising use of energy drinks and foods has led to increased emergency department visits due to caffeine toxicity, with symptoms ranging from palpitations and tremor to ventricular dysrhythmias and seizures. In addition, several deaths have occurred in conjunction with energy drink use [55]. The combined use of energy drinks with alcohol is of particular concern, with some evidence to show that the combination leads to decreased fatigue from alcohol intoxication and an increased desire to continue drinking with potential for increased risky behaviors [56].

Management of caffeine intoxication follows the same principles as theophylline intoxication. Patient stabilization includes treatment of life-threatening seizures and cardiac dysrhythmias. Activated charcoal should be administered as soon as possible to provide gastrointestinal decontamination. Aggressive antiemetic therapy should be administered. MDAC is presumed to be equally effective for caffeine intoxication. Caffeine can be eliminated via hemodialysis; this procedure should be considered in those with seizures, cardiac dysrhythmias, or serum caffeine concentrations in excess of 100 μg per mL.

15. Faber MS, Jetter A, Fuhr U: Assessment of CYP1A2 activity in clinical

Natural opioids (e.g., morphine and codeine) are harvested from the seedpods of the poppy plant *Papaver somniferum*. Semisynthetic opioids (e.g., dextromethorphan, heroin, hydrocodone, hydromorphone, oxycodone, and oxymorphone) are derivatives of morphine, whereas synthetic opioids (e.g., buprenorphine, butorphanol, diphenoxylate, fentanyl, meperidine, methadone, nalbuphine, pentazocine, propoxyphene, and tramadol) are not.

Clandestine laboratories have produced potent opioids as new manufacturing methods have been developed to circumvent the use of controlled or unavailable precursor compounds. Because these xenobiotics may contain a wide variety of active ingredients, adulterants, and contaminants, the clinical syndromes seen in the abuser may be only partly related to the opioid component.

**PHARMACOLOGY**

Opioids interact with central nervous system (CNS) receptors to produce their analgesic, euphoric, and sedative effects. Historically, on the basis of animal studies, three major opioid receptors designated as *mu*, *kappa*, and *sigma* have been proposed. The *sigma* receptor is no longer considered an opioid subtype, because it is insensitive to naloxone, has dextrorotatory stereochemistry binding, and has no endogenous ligand. The International Union on Receptor Nomenclature recommends a change from the Greek alphabet to one similar to other neurotransmitter systems; receptors are denoted by their endogenous ligand (opiates peptides) with a subscript denoting their order of discovery: *delta* to OP$_1$, *kappa* to OP$_2$, and *mu* to OP$_3$ (Table 119.1).

**TABLE 119.1 Opiate Receptor**
Most opioid analgesics are well absorbed after parenteral administration, from the pulmonary capillaries and mucosal sites. Analgesia is promptly achieved after parenteral administration and within 15 to 30 minutes after oral dosing. Peak plasma levels are generally attained within 1 to 2 hours after therapeutic oral doses. However, acute overdose may produce decreased intestinal peristalsis, resulting in delayed and prolonged absorption. Therapeutic and toxic serum xenobiotic concentrations are not well established.

All opioids undergo hepatic biotransformation, including hydroxylation, demethylation, and glucuronide conjugation. Considerable first-pass metabolism accounts for the wide variations in oral bioavailability noted with xenobiotics such as morphine and pentazocine. Only small fractions of the parent xenobiotic are excreted unchanged in the urine. Active metabolites can contribute to the toxicologic profile of specific xenobiotics.

All opioids elicit the same overall physiologic effects as morphine, the prototype of this group. A typical morphine dose (5 to 10 mg) usually produces analgesia without altering mood or mental status in a patient.
Sometimes dysphoria rather than euphoria is manifest, resulting in mild anxiety or a fear reaction. Nausea is frequently encountered, and vomiting is occasionally observed. Morphine and most of its congeners cause miosis in humans. This effect is exacerbated after an overdose, resulting in profound pupillary constriction, predominantly a central effect. Cerebral circulation does not appear to be altered by therapeutic doses of morphine unless respiratory depression and carbon dioxide retention result in cerebral vasodilation.

Respiratory failure is the most serious consequence of opiate overdose. Opioid agonists reduce the sensitivity of the medullary chemoreceptors in the respiratory centers to an increase in carbon dioxide tension and depress the ventilatory response to hypoxia. Even small doses of morphine depress respiration, decreasing minute, and alveolar ventilation. The peak respiratory-depressant effect is usually noted within 7 minutes of intravenous (IV) morphine administration, but may be delayed up to 30 minutes if the drug is intramuscularly administered. Normal carbon dioxide sensitivity and minute volume usually return 5 to 6 hours after a therapeutic dose.

Therapeutic opiate doses cause arteriolar and venous dilation, and may result in a mild decrease in blood pressure. This change in blood pressure is clinically insignificant while the patient is supine, but significant orthostatic changes are common. Hypotension appears to be mediated by histamine release. Myocardial damage in opiate overdose associated with prolonged hypoxic coma may be mediated by cellular components released during rhabdomyolysis, direct toxic effects, or hypersensitivity to the opioids or adulterants.

Heroin (diacetylmorphine) has two to five times the analgesic potency of morphine. Virtually all street heroin in the United States is produced in clandestine laboratories and adulterated before distribution (Table 119.2). The purity of street heroin is between 5% and 90%. Physiologically, the effects of heroin are identical to those described for morphine. Heroin can be administered intravenously, intranasally, or inhaled as a volatile vapor, and can be mixed with other drugs of abuse, typically amphetamine or cocaine (speed ball). The plasma half-life of heroin is 5 to 15 minutes. Heroin is initially deacetylated, in the liver and plasma, into 6-monoacetyl-morphine (6-MAM) and subsequently into morphine [1]. Morphine is mostly metabolized in both liver and brain by enzymatic-dependent glucuronidation activities that produce morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G). An individual variation in sensitivity and tolerance makes correlation of serum levels with clinical symptoms difficult.
The initial heroin “rush” is owing to its high lipid solubility, rapid penetration into the CNS, and its rapid conversion to 6-MAM. The majority of its lasting effects are attributed to its metabolite morphine, and in patients with acute kidney failure the lasting effects appear to be derived from M6G. M3G has virtually no affinity for OP₃ receptors, and its accumulation is believed to be related to neurotoxic effect of long-term morphine use (e.g., myoclonus and neuroexcitatory behavior).

Codeine (methylmorphine) is formulated as a sole ingredient and in combination with aspirin or acetaminophen. Codeine is rapidly absorbed by the oral route, producing a peak plasma level within 1 hour of a therapeutic dose. Usually 10% of codeine is metabolized to morphine by CYP2D6; this may be greatly increased in patients with duplicated or amplified CYP2D6 genes, resulting in opioid toxicity [2]. Clearance of codeine by CYP3A4 may be inhibited by clarithromycin and voriconazole. Codeine and morphine appear in the urine within 24 to 72 hours. However, only morphine is detected in the urine at 96 hours. The effect of codeine on the CNS is comparable with, but less pronounced than that of, morphine. Fatal ingestions with codeine alone are rare.

Fentanyl, a phenylpiperidine derivative, has a potency 200 times that of morphine. Legitimate use is limited to anesthesia, and it is known to be commonly abused by hospital personnel. Rapid IV administration may result in acute muscular rigidity primarily involving the trunk and chest wall, which impairs respiration. Although motor activity resembling seizures have been associated with fentanyl use, simultaneous electroencephalogram recording during fentanyl induction of general

anesthesia failed to show epileptiform activity [3]. This suggests a myoclonic rather than epileptic nature of the observed muscle activity.

Fentanyl is available as a transdermal delivery system that establishes a depot of drug in the upper skin layers, where it is available for systemic absorption. After removal of the patch, serum fentanyl concentrations gradually decline; 50% in 20 to 27 hours. Continued absorption of fentanyl from the skin accounts for a slower disappearance of the drug from the serum than is seen after an IV infusion, where the apparent half-life is 7 hours (range 3 to 12).

By manipulating the chemical structure of fentanyl, α-methylfentanyl (China white), 3-methylfentanyl, and para-fluoro-fentanyl has been produced and distributed on the street as heroin substitutes. They are 200 to 3,000 times more potent than heroin. α-Methyl-acetyl-fentanyl, α-methyl-fentanyl acrylate, and benzylfentanyl are 6,000 times more potent than morphine.

Meperidine, another phenylpiperidine derivative, is less than half as effective when given orally as compared to the parenteral route. Peak plasma levels occur 30 minutes after intramuscular administration, and 1 to 2 hours after an oral dose. The duration of action is 2 to 4 hours. Meperidine is metabolized primarily by N-demethylation to normeperidine, an active metabolite with half the analgesic and euphoric potency of its parent and twice the convulsant property. Excretion is primarily through the kidneys as conjugated metabolites. Typical values of the elimination half-lives of meperidine and normeperidine are 3 to 4 hours and 15 to 30 hours, respectively. Prolonged meperidine administration may lead to normeperidine accumulation, especially in the presence of renal impairment. The neuroexcitatory effects of meperidine toxicity (e.g., agitation, tremors, myoclonus, and seizures) have been attributed to the accumulation of normeperidine [4].

A synthetic meperidine analog, methyl-phenyl-propionoxypiperidine, a contaminant produced during the clandestine synthesis of this agent, led to an epidemic of Parkinsonism among IV drug abusers within days of repeated injections [5].

Diphenoxylate is structurally similar to meperidine. Diphenoxylate (2.5 mg) is formulated with 0.025 mg atropine sulfate (Lomotil) and used in the treatment of diarrhea. In therapeutic doses, the drug has no significant CNS effects. Signs and symptoms arising from a toxic ingestion, primarily reported in pediatric patients, may be delayed because of decreased gastrointestinal (GI) motility and accumulation of the hepatic metabolite difenoxin, a potent opioid with a long serum half-life [6].

Methadone is used for chronic pain conditions and maintenance of opiate addicts. It is well absorbed orally, producing a peak plasma level within 2 to 4 hours. It has a prolonged but variable serum half-life with
mean estimates between 15 and 55 hours, and is usually assumed to be 24 hours, but may have a median elimination half-life of 48 hours in patients on long-term maintenance therapy [7]. The principle enzyme system responsible for methadone metabolism is CYP3A4; other main enzymes responsible are CYP2D6 and CYP1A2. Xenobiotics that interact with these enzyme systems may precipitate withdrawal (e.g., CYP3A4 induction, rifampicin, and fluconazole) or enhance the risk of overdose (e.g., CYP3A4 substrates or inhibitors, fluoxetine, and fluvoxamine). A protracted clinical course is expected following an overdose.

Propoxyphene is structurally related to methadone. It is available alone or in combination with aspirin or acetaminophen. Oral administration is followed by rapid absorption, with peak serum levels occurring in 1 hour. The plasma half-life of propoxyphene and its main active metabolite, norpropoxyphene, is 6 to 12 hours and 37 hours, respectively. Norpropoxyphene is the primary metabolite excreted in the urine [8]. It is believed to play a role in the prolonged clinical course after an overdose.

Pentazocine is a synthetic analgesic in the benzomorphan class and has been involved in the drug abuse trade. It has agonist as well as weak antagonist activity at the opioid receptors. It has one-third the analgesic potency of morphine. When orally administered, pentazocine achieves peak plasma levels within 1 hour and is extensively metabolized in the liver with the parent compound and metabolites detectable in either urine or plasma [9]. Pentazocine, in combination with the antihistamine tripelennamine, is known on the street as T’s and Blues and is used as a heroin substitute [10]. In an attempt to curtail pentazocine abuse, the oral preparation was reformulated to contain 0.5 mg naloxone. When it is parenterally administered, the effects of pentazocine are antagonized by naloxone, which has precipitated withdrawal in opiate-dependent individuals. Because the duration of action of pentazocine exceeds that of naloxone, delayed respiratory depression may occur.

Dextromethorphan, an analog of codeine, is found in a large number of nonprescription cough and cold remedies. It is available as a single ingredient but usually formulated in combination with sympathomimetic and antihistamine xenobiotics. Dextromethorphan is well absorbed from the GI tract, with peak plasma levels occurring 2.5 and 6.0 hours after ingestion of regular and sustained-release preparations, respectively. Dextromethorphan is rapidly metabolized to dextrorphan by hepatic CYP2D6 with a plasma half-life of 2 to 4 hours, and the level of dextrorphan may be highly variable depending on a person’s CYP2D6 genotype [11]. Both dextromethorphan and dextrorphan are noncompetitive antagonists of the N-methyl-D-aspartate (NMDA) receptor as well as serotonin reuptake inhibitors. Animal data suggest the physical effects of dextromethorphan and its abuse potential are caused
by dextrorphan [12]. Within the therapeutic dose, dextromethorphan lacks analgesic, euphoric, and physical dependence properties.

Hydromorphone and oxycodone are orally administered opioids used in the treatment of chronic pain conditions. A number of sustained-release formulations are available, and can result in prolonged poisoning in overdose. The sustained-release properties of some formulations of oxycodone can be circumvented by crushing or dissolving the tablet, resulting in fatal narcotic overdoses among drug abusers [13].

Tramadol is structurally similar to morphine. It is a centrally acting analgesic with moderate affinity for OP3 receptors. The metabolite, O-demethyl-tramadol, appears to have a higher affinity than the parent compound. Most of the analgesic effects are attributed to nonopioid properties of the drug, probably by blocking the reuptake of biogenic amines (e.g., norepinephrine and serotonin) at synapses in the descending neural pathways, which inhibits pain responses in the spinal cord [14].

Buprenorphine is a partial agonist activity with high affinity to, and slow dissociation from, the OP3 receptor. It displaces other opioids and its dose–response curve has a ceiling effect, resulting in less respiratory depression in overdose, although apnea may still occur [15,16]. It has poor oral bioavailability and is administered sublingually. It is also formulated with naloxone that is active only if intravenously administered. Other partial agonists include butorphanol and nalbuphine. They can precipitate opioid withdrawal (see Chapter 126) in those taking other opioids.
CLINICAL PRESENTATION

Miosis, respiratory depression, and coma are the hallmarks of opiate intoxication, with the magnitude and duration of toxicity dependent on the dose and degree of tolerance. The clinical effects of an overdose with any one of the agents in this class are similar. However, there are important differences between certain xenobiotics. Overdoses resulting in toxicity often have a prolonged clinical course, in part because of opiate-induced decreased GI motility when taken orally and prolonged half-life of the xenobiotic or its active metabolite(s). Miosis is considered a pathognomonic finding in opiate poisoning, with the exception of meperidine, propoxyphene, pentazocine, and dextromethorphan use, in the case of a mixed overdose with an anticholinergic or sympathomimetic drug, or when severe acidemia, hypoxemia, hypotension, or CNS structural disorder is present.

CNS depression occurs in most severely intoxicated patients. However, codeine, meperidine, and dextromethorphan intoxications are remarkable for CNS hyperirritability, resulting in a mixed syndrome of stupor and delirium. In addition, the patients with meperidine toxicity may also have tachypnea, dysphoric and hallucinogenic episodes, tremors, muscular twitching, and spasticity, whereas the patients with dextromethorphan toxicity may also manifest restlessness, nystagmus, and clonus [17].

Pulmonary edema may complicate the clinical course of opioid overdose and appear more prevalent with heroin, morphine, codeine, methadone, and propoxyphene. Pulmonary edema has occurred in postoperative patients who received naloxone and after naloxone therapy in overdose patients [18,19]. Typically, the patient has a depressed consciousness and respiration. After naloxone administration, the patient awakens and over minutes to hours is noted to become hypoxic and develop pulmonary edema. Acute naloxone-induced withdrawal has been associated with massive CNS sympathetic discharge, which may be a precipitating factor in the development of neurogenic pulmonary edema [18]. It appears the acute lung injury is at the alveolar–capillary membrane, resulting in manifestations consistent with acute respiratory distress syndrome.

The patients with heroin-induced pulmonary edema typically have normal capillary wedge pressures and elevated pulmonary arterial pressures [20]. In contrast, elevated systemic, pulmonary arterial, and pulmonary capillary wedge pressures and total systemic vascular resistance are seen with pentazocine dosing [21]. This effect is believed to result from transient endogenous catecholamine release. Adulterants in
street drugs are potential pulmonary irritants and toxins, and may cause dyspnea, hypoxemia, and the presence of multiple reticulonodular infiltrates on chest radiograph. A summary of the potential pulmonary complications associated with opioid abuse is provided in Table 119.3.

Heroin toxicity may be associated with cardiac conduction abnormalities and dysrhythmias, which may be the result of metabolic derangements associated with hypoxia, a direct effect of the abused agent, or adulterants (e.g., quinine) in street drugs [22].

Leukoencephalopathy associated with inhalational abuse of heroin (chasing the dragon) typically progresses for several weeks. Initially, cerebellar ataxia and motor restlessness may be followed by the development of pyramidal tract lesions, pseudobulbar reflexes, spastic paresis, myoclonic jerks, and choreoathetoid movements. A quarter of patients may progress to hypotonic paresis, akinetic mutism, and death [23].

Seizures and focal neurologic signs are usually absent with opioid intoxication unless it is complicated by events such as severe hypoxia and an intracranial process (e.g., brain abscess and subarachnoid hemorrhage), when proconvulsive adulterants or when opioids such as meperidine, propoxyphene, pentazocine (T’s and Blues), and tramadol are involved [10,24–26]. Meperidine- and propoxyphene-related seizures may become more frequent in chronic drug abusers with renal insufficiency.
Disabling myoclonus has been reported after several days of fentanyl therapy by the transdermal delivery system [27].

The clinical course after propoxyphene overdose may be severe and rapidly progressive and include seizures, respiratory failure, cardiac dysrhythmias, and circulatory collapse [28]. Propoxyphene appears to be responsible for CNS toxicity (e.g., respiratory depression and seizures) as well as cardiac toxicity (e.g., QRS prolongation and dysrhythmias), whereas norpropoxyphene contributed only to the cardiotoxicity [29]. Cardiotoxicity may be exacerbated by hypoxia or adulterants (e.g., quinine) in street drugs.

Anxiety, dysphoria, and hallucinations are more common with pentazocine than with other opiate derivatives [9]. Acute toxicity in combination with tripelennamine (T’s and Blues) results in the typical opiate intoxication syndrome as well as dyspnea, hyperirritability, hypertension, and seizures. It is believed that these effects may be directly related to tripelennamine [10].

Hypotension may occur after opiate overdose, although pentazocine intoxication may result in hypertension [10]. Electrocardiographic abnormalities associated with heroin overdose include nonspecific ST-segment and T-wave changes, sinus tachycardia, atrial fibrillation, and ventricular tachycardia, and may be related to hypoxemia, direct effects of heroin, its metabolites, or adulterants (e.g., quinine) in street drugs [22].

CNS manifestations are the primary presenting symptoms of patients acutely intoxicated on dextromethorphan and include euphoria, altered mental status (ranging from somnolence to hyperexcitability), dissociative stupor, depersonalization, disorientation, paranoia, dyskinesia, ataxia, nystagmus, disordered speech, vivid auditory, and visual hallucinations [11,12]. These effects appear to be dose-related. Respiratory depression, tachycardia, hypertension, seizures, and death may result from severe acute dextromethorphan intoxication, whereas chronic dextromethorphan abuse is associated with frank psychosis. Dextromethorphan abuse may be associated with a psychologic as well as physiologic dependence syndrome. Chronic dextromethorphan hydrobromide abuse can also cause bromide poisoning [12]. Typical symptoms of bromide toxicity include impaired CNS function including behavioral changes, headache, apathy, irritation, weight loss, acneiform rash, slurred speech, psychosis, tremulousness, ataxia, hallucinations, and coma.

Methadone can produce bradycardia, QTc prolongation, and torsades
de pointes. QTc prolongation and torsades de pointes have been associated with mean daily methadone dose 397 ± 238 mg; mean QTc interval on presentation was 615 ± 77 ms. In one case series, the majority of patients were receiving a potentially QT-prolonging xenobiotic, 41% of the patients had hypokalemia, and 18% of the patients were found to have structural heart disease [30]. A proposed mechanism is inhibition of the cardiac potassium channel by the nontherapeutic (S)-methadone isomer [31]. This isomer is metabolized by CYP2B6; 6% of the population are slow metabolizers, resulting in elevated levels of (S)-methadone and increased QTc intervals [31,32].

The onset of anticholinergic and opioid effects may be significantly delayed after a diphenoxylate overdose [6]. Atropine effects (e.g., CNS excitement, hypertension, fever, and flushed dry skin) may occur before, during, or after opioid effects. However, opioid effects (e.g., CNS and respiratory depression with miosis) may predominate or occur without signs of atropinism.

Following a tramadol overdose, the patients may present with signs and symptoms that include tachycardia, hypertension, respiratory depression, lethargy, agitation, seizures, coma, and metabolic acidosis [26]. Tramadol-associated seizures are reported to be self-limited.

Interaction between meperidine and monoamine oxidase inhibitors (MAOIs), dextromethorphan and MAOIs, and tramadol and selective serotonin reuptake inhibitors may result in the serotonin syndrome [33,34]. The patients with severe serotonin syndrome exhibit rapid onset of altered mental status, muscle rigidity, hyperthermia, autonomic dysfunction, coma, seizures, and death.

Rhabdomyolysis, hyperkalemia, myoglobinuria, and acute renal failure may complicate the clinical course of an acute opioid overdose [35]. Acute renal failure may be owing to direct insult by the abused substance, adulterants in street drugs, and prolonged coma. Chronic parenteral drug use may result in glomerulonephritis and renal amyloidosis and has been associated with concurrent bacterial infections [36]. Potential lethal acute infections have been associated with clostridia contamination [37].

Body packers or “mules” are people who transport large number of concentrated heroin packets in their GI tract from one country to another. If one of these packets ruptures, the amount of drug released may cause severe and prolonged toxicity [38]. They may also develop features of intestinal obstruction, intestinal perforation, and peritonitis [39].
Laboratory studies such as complete blood cell count, serum electrolytes, blood urea nitrogen, creatinine and creatine phosphokinase, urinalysis, arterial blood gas, electrocardiography, chest and abdominal radiography, head computed tomography, and lumbar puncture should be obtained as clinically indicated. Arterial blood gas usually reflects hypoventilation, respiratory acidosis, and metabolic acidosis [40]. If pulmonary edema develops, chest radiographs typically reveal bilateral fluffy alveolar infiltrates, occasionally unilateral in nature, and echocardiograms show normal cardiac function [41]. A negative anion gap with hyperchloremia should raise the suspicion of bromide poisoning from chronic dextromethorphan use, and can be confirmed by a serum bromide level [12]. Chest radiographic findings of pulmonary edema usually resolve within 24 to 48 hours.

It is recommended that an ECG be obtained prior to commencing methadone therapy and within 30 days of commencement and then yearly to monitor the QTc interval [42].

Leukoencephalopathy associated with inhalational abuse of heroin appears as hypoattenuation in the affected white matter, although this may not be apparent until late in the disease. Magnetic resonance imaging typically demonstrates white matter hyperintensity on T2-weighted sequences. The affected areas are initially the occipital and cerebellar white matter, followed by involvement of the parietal, temporal, and frontal lobes. The cerebellar peduncles, splenium of the corpus callosum, posterior limb of the internal capsules, corticospinal tract, medial lemniscus, and tractus solitarius may also be involved [23].

Quantitative serum opiate levels do not contribute to patient management. A urine toxicology screen may confirm the diagnosis, but is rarely necessary for acute patient management. Commercial opioid assays are unlikely to detect synthetic opioids. The metabolites of naloxone are chemically related to oxymorphone, but naloxone is not known to give false-positive immunoassay urine screens for opioid substances [43]. False-positive serology tests for syphilis have been reported among drug addicts [44]. Laboratory investigation should also include tests for infection in patients with fever (Table 119.4).

MANAGEMENT

A diagnosis of opioid poisoning should be considered in all comatose patients. However, the classic triad of opiate toxicity (coma, miosis, and respiratory depression) may not be apparent after a mixed overdose. Respiratory support is paramount in the management of patients with opioid toxicity; one should secure the airway and ventilate with 100% oxygen. Vascular access should be established. The patient should be placed on continuous pulse oximetry and cardiac monitoring. Vital signs should be monitored frequently.

Naloxone is a specific opiate receptor antagonist and can reverse the analgesia, respiratory depression, miosis, hyporeflexia, and cardiovascular effects of opiate toxicity [45]. The goal of naloxone therapy is to re-establish adequate spontaneous ventilation. The initial IV naloxone dose should be 0.1 mg if the patient is possibly opioid dependent; larger doses may precipitate acute opioid-withdrawal syndrome. Otherwise, an initial 2 mg dose can be administered. If there is history of an opiate exposure, a strong suspicion based on presenting signs and symptoms, or a partial response to the initial naloxone dose, repeated IV naloxone boluses up to 10 mg should be administered because methadone, pentazocine, propoxyphene, diphenoxylate, and sustained-release preparations of oxycodone and hydromorphone may not respond to the usual naloxone doses [46]. Despite its strong affinity to OP₃ receptors, buprenorphine overdose can be treated effectively with usual doses of naloxone [16].

Intramuscular, intralingual, endotracheal, intraosseous, and intranasal routes of naloxone administration are acceptable alternatives when IV access is not readily available [47–49]. Repeat naloxone boluses may be required every 20 to 60 minutes because of its short elimination half-life (60 to 90 minutes). A continuous naloxone infusion may be considered for patients who have a positive response but require repeated bolus doses because of recurrent respiratory depression [50]. A therapeutic continuous naloxone infusion can be made by administering two third of the effective naloxone bolus dose per hour (see Chapter 125-Antidotes). The infusion is titrated to maintain adequate spontaneous ventilation without precipitating acute opioid withdrawal and empirically continued for 12 to 24 hours. The patient should be admitted to an intensive care or high-dependency setting for continuous monitoring. After the naloxone
therapy is discontinued, the patient should be carefully observed for 4 hours for recurrent respiratory depression.

Nebulized naloxone, 2 mg mixed with 3 mL normal saline delivered by a nebulizer face mask with the side ports partially occluded with tape to prevent excessive loss of medication, appears to be a safe and effective treatment of suspected opioid overdose in patients with a minimum respiratory rate of 6 breaths per minute [51].

Naloxone is effective in reversing diphenoxylate-induced opioid toxicity. However, recurrence of respiratory and CNS depression is common [6]. All patients with significant diphenoxylate overdose should be observed in an intensive care setting for at least 24 hours. The value of naloxone use for dextromethorphan toxicity is debatable [12].

Hypotension may respond to naloxone therapy but may require fluid resuscitation and vasopressors. Overzealous fluid resuscitation should be avoided because of the risk of pulmonary edema.

The management of seizures should follow current treatment guidelines and include benzodiazepines or barbiturates. Adjunct naloxone therapy may be effective in propoxyphene, but not in meperidine- or tramadol-related seizures [52]. Seizures have been reported after naloxone administration for tramadol overdose [26].

The patients with significant CNS signs or symptoms from bromide toxicity may require urgent hemodialysis for bromide removal.

The management of serotonin syndrome is primarily supportive (see Chapters 104 and 185); and in severe toxicity ICU admission, intubation and neuromuscular paralysis, active cooling, and 5-HT_{2A} antagonists treatment may be necessary (e.g., cyproheptadine 12 mg orally or by nasogastric tube, followed by 4 to 8 mg every 6 hours or chlorpromazine 12.5 to 25 mg IV, followed by 25 mg every 6 hours) [53].

GI decontamination should be considered for orally administered opioids after vital signs have been stabilized. The clinical benefits of multiple oral doses of activated charcoal are unproven, but it is potentially beneficial because of the prolonged absorption phase that is typically encountered with opiate overdoses. Repeat charcoal doses should not be used in the absence of active bowel sounds.

The management of pulmonary edema should include adequate ventilation, oxygenation, and low tidal volume positive-pressure ventilation as needed [54]. Inotropic agents and diuretics appear to be of little value.

Bradycardia secondary to methadone administration responds to ceasing the drug; atropine has not been utilized. If the patients receiving methadone develop a QTc interval of more than 500 milliseconds, consideration should be given to reducing the dose or discontinuing the drug [42].

Asymptomatic body packers should be conservatively managed when
the condition of packaging does not appear to be compromised. One proposed guideline involves the oral administration of a water-soluble contrast solution followed by serial abdominal radiographs (Table 119.5) [55]. Whole-bowel irrigation (WBI) with polyethylene glycol electrolyte lavage solution (PEG-ELS) has also been advocated on the basis of case reports [56].

### Table 119.5 Medical Management for Asymptomatic Body Packers

1. Administer an oral dose of water-soluble contrast (e.g., Gastrografin): 1 mL/kg
2. Perform abdominal radiographs (supine and upright) at least 5 h after oral contrast administration
3. If radiographs are positive, perform daily abdominal radiographs, and after a spontaneous bowel movement
4. All bowel movements are checked for drug packets
5. The patient may be discharged after passage of two packet-free bowel movements and negative abdominal radiographs

*a*The patients are permitted to feed normally, and vascular access should be maintained.

Pruritus is a common opioid adverse event. It may be localized or general, and ranges from mild to severe. Antihistamines are usually ineffective, but naloxone has frequently been found to offer relief. Ondansetron has been reported to provide relief in refractory cases [57].

Leukoencephalopathy associated with inhalational abuse of heroin has been reported to improve following the antioxidant ubiquinone (coenzyme Q10) administration in doses of 30 to 300 mg QID [58].

Nalmefene is also effective for the reversal of opioid-induced CNS effects and can be administered orally or intravenously. Its half-life and dose-dependent duration of action are 4 to 8 hours after IV administration [59]. The initial adult dose is 0.5 mg for those who are not opioid dependent and 0.1 mg for those suspected of having opioid dependency. If there is an incomplete response or no response, additional doses can be given at 2- to 5-minute intervals. A total dose of 1.5 mg may
be necessary to exclude the possibility of opioid poisoning. The principal advantage over naloxone is its considerably longer duration of antagonistic action. However, withdrawal syndromes precipitated by nalmefene use would also be prolonged.

Naltrexone is a potent, long-acting pure opiate antagonist that is effective orally. Its use is primarily limited as adjunctive therapy for opioid detoxification. Naltrexone may induce a withdrawal syndrome that lasts up to 72 hours.
REFERENCES

1987.

A pesticide is as an agent intended for killing, preventing, repelling, or mitigating any pest. Despite their inherit toxicity, pesticide usage continues to increase; environmental contamination and reports of epidemic pesticide poisoning are inevitable. The health consequences from the long-term and low-level exposure to these chemicals, such as carcinogenesis, teratogenicity, reproductive disorders, and neurologic sequelae, may be significant and difficult to measure. In many countries in which there are limited regulations on pesticide usage, pesticide ingestion is one of the leading forms of suicide, and pesticide exposure is a major occupational risk. Even in the United States, pesticide exposures remain a major public health problem. Worldwide statistics on pesticides poisonings are limited because of gross under reporting in developing countries. Conservative estimates for suicides from pesticides worldwide exceeded 250,000 deaths annually [1].

This chapter focuses on selected pesticides that are most clinically important. Some of the common pesticides are provided in Table 120.1. Organophosphate insecticides are covered in Chapter 109. Further information on the identification and toxicity of pesticide products may be obtained from sources such as material data safety sheets, Hayes’ Handbook of Pesticide Toxicology, Farm Chemicals Handbook, and the pesticide label database (http://www.cdpr.ca.gov/docs/label/labelque.htm).

ORGANOCHLORINES

Organochlorine compounds are commonly used as insecticides, soil fumigants, solvents, and herbicides. Human toxicity can result from either acute or chronic exposure. Contamination typically occurs during production or application of these agents. Infants and toddlers are at risk for toxicity from bioaccumulation in foodstuffs and excretion in breast milk. Maternal exposure is important because these compounds can be concentrated in fetal tissues. These toxicants can cause a variety of systemic manifestations, but are most notable for their central nervous system (CNS) effects. Organochlorines can be divided into four structural categories: dichlorodiphenyltrichloroethane (DDT) and related agents, hexachlorocyclohexanes, cyclodiene, and toxaphenes. Chlordane, chlordene (Kepone), DDT, dieldrin, endrin, heptachlor, kevelan, methoxychlor, and mirex are no longer being used or registered for use in the United States.

Pharmacology

The organochlorines are well absorbed from the gastrointestinal (GI) tract. For example, death can occur within 2 hours of intentionally ingesting endosulfan, and most deaths associated with chlordane have been from oral exposures by children. The serum half-lives of these chemicals are long, varying from days to months, because of their high lipid solubility. This allows these agents to be stored in fatty tissues (e.g., brain) with the resultant delays in clearance. The organochlorines are known to concentrate in breast milk and fetal tissues. At delivery, it has been shown that fetal blood and tissue had higher concentrations of lindane (γ-hexachlorocyclohexane, Kwell) than maternal samples [2,3]. However, teratogenic effects have not been demonstrated in the limited number of animal studies performed [4].

Organochlorines are metabolized by the hepatic cytochrome P450 (CYP) enzymes in the liver. Toxaphene, chlordane, DDT, and lindane can induce CYP activity and affect not only their own metabolism but also the effects of coadministered medications [5].

Chlordane has several metabolites, such as heptachlor, oxychlordane, and heptachlor epoxide. Most of the available information on chlordane and metabolite tissue distribution is from case reports of unintentional and suicidal exposures. Depending on the source, the elimination half-life
of chlordane varies from 21 to 88 days [6,7]. Most of the chlordane and metabolites are excreted by the biliary system. On absorption into the body, aldrin is rapidly metabolized to the epoxide derivative, dieldrin. Because very little of aldrin remains, its toxicity is attributed to dieldrin. Dieldrin is stored in fatty tissues, and its elimination half-life in humans is approximately 369 days [8]. Endrin, an isomer of dieldrin, is rapidly metabolized in both humans and animals, with an elimination half-life of 2 to 6 days [9].

Organochlorines have several mechanisms of action. They alter sodium and potassium channel activity and ion movement across the neuronal membranes and can be toxic to axons. For example, DDT facilitates sodium ion transport and inhibits potassium transport. This can result in spontaneous firing and prolongation of action potentials and repetitive firing after a stimulus. DDT also inhibits Na+/K+ adenosine triphosphatase and calmodulin activities, which can reduce the rate of neuronal repolarization. This may account for some of the neurologic manifestations such as paresthesias, thought disturbances, myoclonus, and seizures. Cyclodienes, hexachlorocyclohexanes, and toxaphene manifest neurotoxicity by inhibiting γ-aminobutyric acid receptor function in the CNS. In the limbic system, lindane can directly excite neurons and result in agitation and seizures [10]. Abnormalities in respiratory rate patterns can result from direct medullary toxicity or pulmonary aspiration. The level of toxicity of the various organochlorines can be categorized into high, moderate, and low (Table 120.2).

**Clinical Toxicity**

Poisoning can result from ingestion, dermal absorption, or inhalation. Inadvertent human exposures to aldrin and dieldrin have resulted from pesticide spraying and mixing which causes dermal and inhalational absorption. The use of lindane in home vaporizers has resulted in
significant inhalation toxicity. Agents such as dieldrin, lindane, and Kepone have good dermal penetration. As little as two total body applications on two successive days of 1% lindane (Kwell), a common scabicide, resulted in seizures in an 18-month-old child [11]. The peak concentration of lindane occurs 6 hours after dermal application; thus, delayed and prolonged manifestations of toxicity may occur from dermal absorption. Workers who directly handled lindane had health complaints of headaches, paresthesias, tremors, confusion, and memory impairment [12]. Also, seizures have been reported by occupational surveys among sprayers and applicators of aldrin and dieldrin [13]. Dermatitis can occur from the topical exposure dicofol and methoxychlor. Intradermal and subcutaneous injections of these agents can result in chemical dermatitis and sterile abscesses [14]. Dicofol and methoxychlor have minimal toxicity.

Seizures are the most prominent CNS effect of these agents. The seizures occur soon after exposure, may present without a prodrome, and can be protracted in frequency [9]. Late-onset seizures may result from delayed GI or dermal absorption. Acute exposures to DDT present initially with tremors, nausea, vomiting, muscle weakness, and confusion, which may progress to seizures [15]. Among the organochlorines, both psychomotor agitation and CNS depression have been described. Chlordecone, mirex, and endosulfan are more likely to cause tremors and agitation than seizures. Kelthane, perthane, methoxychlor, and lindane are more likely to cause CNS sedation than excitation. Endrin is considered one of the most toxic of the cyclodienes, with reports of hyperthermia and decerebrate posturing [9]. In 1984, an outbreak of endrin toxicity from contaminated foodstuffs occurred in Pakistan, where seizures resulted in a 10% mortality rate [16].

Neurologic symptoms resolve quickly because of rapid distribution of the organochlorines from blood to lipid stores. Because redistribution back into the blood pool can occur at a later time, continual observation of the patient for delayed toxicity may be warranted. Some of the long-term CNS effects (i.e., thought disturbances) after significant exposures may be owing to direct chemical toxicity or anoxic encephalopathy from sustained seizures. Chlordecone is a recognized neurotoxin, causing peripheral neuropathies [17].

Nausea, vomiting, and diarrhea may occur after ingestions, especially if petroleum distillates are part of the preparation. Pulmonary aspiration of these agents can cause tachypnea and significant respiratory distress, with resultant pulmonary edema. When dicofol is heated or comes in
contact with an acid, it decomposes to hydrogen chloride, which causes respiratory irritation [9]. Hypersensitivity pneumonitis may result from inhalational exposures when the organochlorine is mixed with pyrethrins. Hypotension with decreased cardiac output and a prolonged QT interval have been reported from endosulfan poisoning [18].

Significant elevations of liver enzymes were reported in a group of 19 workers with a 10-year exposure to lindane [19]. Acute oral exposures to lindane in animals may cause fatty degeneration and necrosis of the liver. From the few reports of human exposures to chlordane, there is little evidence of hepatotoxicity from this agent [20]. Microsomal enzyme induction has been demonstrated in animals that were orally administered chlordane. Long-term exposure among 233 workers with aldrin, dieldrin, endrin, and kelodrin for 4 to 12 years was not associated with any significant elevation of hepatic enzymes or hepatic enzyme induction.

Hematologic dyscrasias, including aplastic anemia, leukopenia, leukocytosis, granulocytopenia, granulocytosis, eosinophilia, thrombocytopenia, and pancytopenia, have been reported after repeated lindane exposures [21]. However, all of the involved preparations also contained benzene, which can account for such findings. Megaloblastic anemia and bone marrow depression have been associated with chlordane exposures. DDT and toxaphene are suspected human carcinogens [22]. The risks for aldrin and dieldrin as human carcinogens could not be determined by IARC (International Agency for Research on Cancer) because of insufficient human and animal data.

**Diagnostic Evaluation**

Serum concentrations of these organochlorines are commonly measured by gas chromatography/mass spectrometry. In an obvious exposure to these agents, these measurements are academic and would not alter clinical management. There are no correlations between concentrations in body tissues and specific health effects. If the diagnosis is in doubt, these measurements can at least confirm or rule out the exposure to the insecticide. Although blood is commonly sampled for the detection of these chemicals, adipose tissue, or human milk may be used as well. The laboratory should be consulted regarding the availability of analytical methods for biologic specimens other than blood. An acute exposure can be determined by a quantitative comparison of parent compound to metabolite. Because DDT and aldrin are rapidly metabolized upon systemic absorption, their elevated concentrations in the blood would support a recent exposure.

Chlorinated hydrocarbons are radiopaque, and their radiopacity is directly related to the number of chlorine atoms per molecule. Thus,
radiographs can assist in demonstrating aspiration pneumonia and gut burden.

Management

Rescue workers and health care providers must use proper equipment, such as gloves and gowns, to prevent unnecessary exposure to these chemicals when providing assistance to these patients. Initial treatment of organochlorine exposure involves limiting further chemical absorption by the patient. The patient should be removed from the scene, disrobed, and thoroughly and repeatedly washed with soap and water. Washing should include hair and fingernails. The patient’s clothing and leather goods must be placed in a plastic bag and discarded because of the tenacious binding of these agents to leather. All wash water should be contained and discarded as hazardous waste by qualified personnel.

The role of gastric decontamination depends on the clinical presentation. Immediately after an intentional ingestion and in asymptomatic patients without spontaneous emesis, gastric aspiration should be carefully performed with a small nasogastric tube. Activated charcoal should be administered soon after ingestion (preferably within 1 hour) because it can limit further gut absorption [23]. Also, cholestyramine may interrupt enteric circulation and enhance elimination. Chlordecone and chlordane undergo enterohepatic circulation, and cholestyramine is indicated in symptomatic patients. In a controlled trial, cholestyramine was administered as 16 g per day to symptomatic factory workers exposed to chlordecone. After 5 months, chlordecone fecal elimination was shown to increase by 3.3 to 17.8 times, with neurologic symptoms improving as concentrations declined [24]. Milk- and oil-based cathartics should be avoided because their high lipid solubility can enhance gut absorption. Hemodialysis is not effective in enhancing elimination of these chemicals because of their high volume of distribution and protein binding [25]. Hemoperfusion is probably of no benefit [25].

Organochlorine-induced seizures are managed with benzodiazepines and barbiturates. Phenytoin has not been demonstrated to be more effective as an anticonvulsant than barbiturates and it may actually increase the incidence of these seizures [26]. For uncontrolled status epilepticus, muscle paralysis, and general anesthesia may be necessary. Aggressive seizure control is warranted to limit further development of CNS damage, metabolic acidosis, hyperthermia, rhabdomyolysis, and myoglobinuric renal failure.
Respiratory distress caused by bronchospasm is managed with humidified oxygen and nebulized bronchodilators. Parenteral administration of adrenergic amines is not recommended because it may potentiate myocardial irritability. Early administration of steroids and prophylactic use of antibiotics for pulmonary aspiration has not been demonstrated to improve patients’ outcomes. The early use of antibiotics may predispose to the selective growth of resistant bacterial organisms.

After appropriate decontamination, asymptomatic patients with an oral exposure can be observed for 6 hours and then discharged if their clinical status remains unchanged. The patients presenting with cardiovascular, CNS, or persistent respiratory manifestations should be admitted for further therapy and observation.
**PYRETHROIDS**

Pyrethrum is a collection of naturally occurring insecticide esters from the chrysanthemum flower. The pyrethrin I ester has the greatest insecticidal activity and is subject to rapid environmental degradation. To enhance their effectiveness in commercial use, synthetic alternatives known as pyrethroids were developed that are more resistant to decay. These compounds are present in consumer products, from flea and tick removers for pets to topical pediculicides.

**Pharmacology**

Pyrethroids can be separated into two classes based on their chemical structures. For example, Type II pyrethroids have a cyano group at the alpha carbon, such as deltamethrin. The pyrethroids (including pyrethrins) delay closure of the sodium channel during the end of depolarization, with resultant insect paralysis. Type I pyrethroids maintain the sodium channel in the open position for a shorter period than Type II pyrethroids. In addition, Type II pyrethroids antagonize inhibitory chloride channels and alter calcium ion transients, but the contribution of these findings to clinical toxicity is unclear. Piperonyl butoxide is commonly added to commercial preparations to inhibit insects’ ability to metabolize the pyrethroid and prolong activity. In mammals, these agents are relatively nontoxic because of the low concentrations and the rapid mammalian metabolism of these chemicals. However, people who are allergic to ragweed may have hypersensitivity reactions to pyrethroids. The degree of this cross-sensitization has been reported to be as high as 46%. Pyrethroids have no effects on cholinesterase activity, and atropine and pralidoxime are not indicated in therapy.

Pyrethroids are readily absorbed from the GI tract. Dermal absorption varies depending on the type of agent and additive organic solvents. Systemic absorption is enhanced in the presence of petroleum distillates. These compounds are highly lipid-soluble and largely metabolized by the mixed-function oxidase enzymes in the liver.

**Clinical Toxicity**

Poisoning from pyrethroids can result from inhalational, dermal, or oral exposures. Nausea, vomiting, and diarrhea may occur after ingestion [27,28]. Neurologic manifestations and hypersensitivity reactions, including anaphylaxis, are the most common forms of systemic toxicity.
Neurologic findings depend on the type and concentration of the pyrethroid and include paresthesias, muscle fasciculations, coma, and seizures [27,28]. For example, poisoned patients tend to present with tremors from Type I pyrethroids and with choreoathetosis and salivation from Type II pyrethroids. The patients with an intentional ingestion of a mixture containing an organophosphate and a pyrethroid can present with predominant cholinergic manifestations.

Management

Treatment is very similar to that described for organochlorines (see previous discussion). GI decontamination may be appropriate but there is no role for repeat-dose–activated charcoal and cholestyramine therapy because enterohepatic circulation has not been demonstrated for the pyrethroids. Hypersensitivity reactions, including anaphylaxis, should be managed with epinephrine, steroids, antihistamines, bronchodilators, and vasopressors, as indicated.

Asymptomatic patients with oral exposures can be observed for 6 hours and medically cleared of toxicity if their clinical status remains unchanged. The patients presenting with cardiovascular, CNS, or persistent respiratory manifestations should be admitted for further therapy and observation. The patients presenting with cholinergic manifestations after a mixed ingestion of pesticides should be treated for organophosphate toxicity (see Chapter 109), which includes pralidoxime and an appropriate amount of atropine to dry secretions.
ANTICOAGULANTS

Bishydroxycoumarin (dicumarol), the first anticoagulant, was isolated as the hemorrhagic agent in sweet clover disease, a bleeding disorder that resulted from the ingestion of spoiled clover silage. Numerous congeners, such as warfarin (3-α-acetonylbenzyl-4-hydroxycoumarin), have since been synthesized and used as rodenticides. Typically, for the bait to be effective, the rodent must consume it for 3 to 10 days; however, continuous feeding for 21 days may be necessary to achieve 100% mortality. As rodents became increasingly resistant, warfarin derivatives were introduced and have supplanted warfarin. These “superwarfarins,” or long-acting anticoagulants, including brodifacoum, difenacoum, and indanedione derivatives, have longer lipophilic phenyl side chains that increase their potency (approximately 100 times more potent than warfarin) and their half-life and duration of action [29]. Most anticoagulant rodenticide is packaged with cereal or other food products as bait, with the amount of rodenticide in the product varying from 0.005% to 0.025% per weight. Acute accidental or suicidal ingestion of a minimal amount of bait containing long-acting anticoagulants is unlikely to cause toxicity [30]. However, a “mouthful” of a long-acting anticoagulant ingestion in an adult human has been reported to cause significant coagulopathy.

Pharmacology

Warfarin and its derivatives are oxidized by CYP hepatic microsomal enzymes into inactive metabolites in the liver. More specifically, warfarin and its enantiomers are metabolized by CYP 2D6, 3A4, and 2C9 [31]. The plasma half-life of warfarin is 42 hours, with duration of action of 2 to 5 days. The long-acting anticoagulants are concentrated in the liver and have extremely long half-lives; brodifacoum has a half-life of 120 days in dogs, 61 hours in rabbits, and 156 hours in rats [32,33]. The half-life of long-acting anticoagulants may be affected by the dose. The exact half-life of long-acting anticoagulants in humans is unknown. Case reports in human exposures have reported half-lives of 6 to 23 days for chlorophacinone and 16 to 39 days for brodifacoum [29,34–36]. Clinical coagulopathy may persist as long as 42 to 300 days [29,34–36].

These anticoagulants inhibit vitamin K 2,3-epoxide reductase and, to a lesser extent, vitamin K reductase. These enzymes are responsible for the cyclic regeneration of vitamin K [37]. Vitamin K is the active coenzyme responsible for activation of clotting factors II, VII, IX, and X, as well as anticoagulant factors protein C and protein S, by hepatic γ-carboxylation.
of the N-terminal glutamate residual of these proteins [37]. Once activated, vitamin K–dependent clotting factors can interact with calcium and phospholipids in the coagulation cascade. Inhibition of vitamin K 2,3-epoxide reductase and vitamin K reductase depletes vitamin K and vitamin K–dependent clotting factors, resulting in coagulopathy and bleeding. The half-lives of vitamin K–dependent clotting factors are 7 hours for factor VII, 24 hours for factor IX, 36 hours for factor X, and 50 hours for factor II [35]. Because factor VII has the shortest half-life of the vitamin K–dependent clotting factors, increases in prothrombin time or international normalized ratio (INR) are not seen until 50% to 70% of factor VII is depleted. In a healthy person, this change occurs 24 to 48 hours after ingestion [29,30]. Clinical coagulopathy may not be evident for several days when the other vitamin K–dependent factors are also depleted, however.

Clinical Toxicity

The primary manifestation of poisoning is coagulopathy. The most common signs are cutaneous bleeding, soft-tissue ecchymosis, gingival bleeding, epistaxis, hematuria, and increased menstrual bleeding [29,34]. Gross hematuria, GI bleeding, hemoptyisis, and peritoneal and diffuse alveolar bleeding may occur in patients with more serious poisoning [29,38]. Fatalities are uncommon and usually result from complications of intracranial hemorrhage [29,39].

Management

Gastric decontamination with activated charcoal should be initiated for acute ingestions. The most important laboratory studies are the prothrombin time and INR. Soon after an acute ingestion, values are expected to be normal; assays must be repeated at least 48 hours after exposure because of delayed coagulopathy. Prophylactic vitamin K therapy can delay the onset of coagulopathy, and is not recommended as it may obscure the diagnosis and mandate prolonged coagulation profile monitoring, which might otherwise be unnecessary. Clotting factor analysis, particularly for factor VII, is a more sensitive and earlier indicator of coagulopathy. Factor analysis does not offer more useful information in most patients with minimal ingestions, however. Occasionally, serum detection for warfarin and its derivatives has demonstrated unsuspected exposures in patients with coagulopathy of unknown cause. In patients with coagulopathy, serial monitoring of warfarin derivative concentrations can assist in predicting the duration of coagulopathy and therapy [35].

The primary treatment of anticoagulant toxicity is vitamin K replacement, which is indicated in patients with evidence of
coagulopathy. Warfarin and its congeners have much less effect on human than on rat vitamin K reductase, thus allowing vitamin K rescue therapy for anticoagulant toxicity in humans. Because a single dose of vitamin K therapy cannot affect the prolonged toxicity of the long-acting anticoagulants, empiric vitamin K therapy is not recommended unless the patient has a coagulopathy. Vitamin K is not immediately effective in reversing coagulopathy; four-factor prothrombin factor concentrates (PCC) are indicated in patients with significant bleeding diathesis (Table 120.3) [40]. Four-factor PCC are preferred over three-factor PCC, which lack factor VII, and activated factor VII [40,41]. PCC are also preferable to fresh frozen plasma (FFP) because of less fluid load, lower infection risk, and more rapid correction of the INR in patients with a coagulopathy from warfarin toxicity [40,41]. PCC contain heparin and may be contraindicated in patients with heparin-induced thrombocytopenia.

__a__Second line therapy: fresh-frozen plasma (15 mL/kg).
Only vitamin K₁ (phytonadione) should be used because the other forms (K₂, K₃, and K₄) are ineffective in the treatment of anticoagulant toxicity. Vitamin K₁ can be administered orally, subcutaneously, intramuscularly, and intravenously. Intravenous administration has been associated with anaphylactoid reactions and death [42]; slow intravenous administration (10 mg over 30 to 60 minutes) is recommended for those with acute bleeding diathesis. Intramuscular injection may cause hematoma formation in patients with coagulopathy. Subcutaneous administration of vitamin K₁ is safe and may be less effective than the oral route [43]. Treatment should be switched to oral vitamin K₁ once bleeding is controlled and the patient’s GI tract deemed intact for oral absorption. The half-life of oral vitamin K₁ is approximately 6 hours [35]. The oral vitamin K₁ dose required to reverse coagulopathy is variable, but typically ranges from 100 to 300 mg per day, divided three to four times per day [29,35]. Once coagulopathy is reversed, the most common maintenance dose for oral vitamin K₁ is 100 mg (range 20 to 300 mg) daily, but can also be divided into two doses daily [29]. The amount of vitamin K therapy must be titrated to clinical response, however. The duration of vitamin K therapy and coagulopathy is also highly variable, ranging from 40 to 300 days [29]. When the patient’s INR has remained normal for several days after stopping the treatment, vitamin K therapy can be discontinued. The trend of the patient’s concentration of clotting factors during this period may assist the determination of this clinical endpoint. Various methods have been proposed to decrease the duration of coagulopathy, including administration of hepatic enzyme inducers such as phenobarbital. There is no good evidence to support any of these therapies, however.
STRYCHNINE

The use of strychnine as a pesticide dates back to the 16th century, when an extract of the Filipino St. Ignatius bean (Strychnos ignatii) was introduced as a rodenticide in Europe. Strychnine was used as a tonic, cathartic, and aphrodisiac as late as 1970, and resulted in numerous deaths [44]. It is also found as an adulterant in illicit drugs, such as cocaine and heroin. The only “legitimate” uses of strychnine today are as a pesticide and in research study of neural transmission.

Pharmacology

Strychnine is rapidly absorbed through the nasal mucosa and orally in the small intestine. It undergoes hepatic oxidative transformation to unknown metabolites, and only 10% to 20% is excreted unchanged in the urine within 24 hours. The half-life of strychnine in humans is 10 to 16 hours, and the volume of distribution is 13 L per kg [45.46].

Strychnine competitively antagonizes postsynaptic glycine receptors at the spinal cord and, to a lesser degree, at the brain stem, cerebral cortex, and hippocampus [44]. Strychnine-binding sites overlap, but are distinct from glycine-binding sites at the glycine receptor [47]. Glycine receptors at the cerebral cortex and hippocampus are of a subtype insensitive to strychnine and are minimally affected [44]. The action of glycine is similar to that of γ-aminobutyric acid in that it enhances chloride ionic channel conduction, resulting in hyperpolarization of postsynaptic membrane and an increased threshold for neurologic transmission [48]. The highest concentration of glycine receptors is found at the ventral horn motor neurons in the spinal cord [48]. Glycine antagonism reduces neuromuscular inhibition, including reciprocal inhibition between antagonistic muscles, resulting in contraction of both flexor and extensor muscle groups [49]. The pharmacologic effect of strychnine is similar to that of tetanus toxin, which inhibits the release of glycine at postsynaptic neurons in the spinal cord [48].

Clinical Toxicity

The onset of toxicity is usually within 15 to 30 minutes of exposure. The lethal dose in adults is typically 50 to 100 mg, but it may be as little as 5 to 10 mg in children. Diffuse muscle contractions and spasms are the primary manifestations of strychnine toxicity. Facial muscle spasms result in risus sardonicus (the “sardonic smile”) and trismus. Opisthotonos, abdominal muscle contractions, and tonic movements of
the extremities may resemble convulsions. Because glycine has limited effects in the higher CNS centers, seizures are unlikely and mental status is normally preserved until the patient is hypoxic or moribund [49]. The extensor muscles appear to be more affected than the flexor muscles because they are the antigravity muscles and generally stronger. Muscle contractions can be triggered or amplified by any stimulations, including auditory, tactile, and visual stimuli, and may lead to lactic acidosis, rhabdomyolysis, and hyperthermia [49,50]. Respiratory depression results from sustained chest and diaphragmatic muscle contractions and brain-stem depression. Death is related to respiratory depression, anoxia, hyperthermia, and complications from significant muscle contractions [45]. The clinical manifestations of strychnine toxicity differ from tetanus infection in that the onset of symptoms of tetanus infection is more gradual and the duration of illness is more prolonged.

Management

Securing the airway, assisting breathing, and maintaining the circulatory system are the immediate goals in symptomatic patients. Electrolytes, acid–base changes, oxygenation saturation, renal function, urine output, and temperature should be monitored carefully in symptomatic patients. GI decontamination should be performed in any case of suspected strychnine ingestion. Enhanced elimination by urinary manipulation has no effect because of minimal renal elimination. Hemodialysis or charcoal hemoperfusion is ineffective because of the large volume of distribution. Termination of muscle contractions prevents or reverses lactic acidosis, rhabdomyolysis, hyperthermia, and respiratory depression. Benzodiazepines are the initial agents of choice in attenuating musculoskeletal signs and symptoms [50,51]. Benzodiazepines enhance γ-aminobutyric acid effects in the spinal cord and may displace strychnine binding to glycine receptors [47,48]. Barbiturates also are reported to be useful in the treatment of strychnine toxicity. These agents may not be completely effective in patients with severe strychnine poisoning, however, and other agents such as propofol and adjunct nondepolarizing neuromuscular blockade may be required [47,51]. Strychnine toxicity usually resolves within 12 to 24 hours [44,51]. Supportive therapy should be continued until the patient is asymptomatic.
SODIUM MONOFLUOROACETATE

SODIUM MONOFLUOROACETATE

Sodium monofluoroacetate is frequently referred to as “compound 1080,” the number assigned to the compound during its initial development. It is the primary toxic constituent in the South African gifblaar (Dichapetalum cymosum), but it is also present in other plants in South America and Australia. Fluoroacetate is highly toxic to all mammals, and its use was banned in the United States in 1972 because of human fatalities and indiscriminate extermination of non-targeted species. The congener sodium fluoroacetamide (compound 1081), also used as a pesticide, has mechanisms and effects similar to those of fluoroacetate. Since 1985, fluoroacetate was re-introduced but restricted to livestock protection collars (tubular collars filled with 1% sodium fluoroacetate solution, which is released when bitten by predators). In Australia and New Zealand, fluoroacetate is still use as a pesticide for control of invasive mammals, such as rabbits, foxes, feral pigs, wild dogs, and possums.

Pharmacology

Fluoroacetate appears to be minimally absorbed through skin but rapidly absorbed from the GI tract. It is metabolized to fluorocitrate in the tricarboxylic acid (TCA) cycle, with 12% of the ingested dose excreted in the urine [52]. In animals with relative resistance to monofluoroacetate, a hepatic defluorination system cleaves the carbon–fluoride bond to detoxify the compound.

Fluoroacetate is structurally similar to acetate and is incorporated into the TCA cycle with the assistance of acetyl coenzyme A. Fluoroacetate combines with citrate to form fluorocitrate in the TCA cycle [53]. Fluorocitrate inhibits aconitase and succinate dehydrogenase and disrupts the TCA cycle, halting cellular respiration and causing cell death [53]. Organs with high metabolic demands, such as the brain and heart, are immediately affected [53]. The lethal dose of sodium monofluoroacetate is 2 to 10 mg per kg.

Clinical Toxicity

The onset of poisoning occurs within 1 to 2 hours of exposure. Nausea and vomiting are followed by CNS and cardiovascular manifestations,
which are the primary toxicities in humans [53,54]. The patient may present with agitation, lethargy, seizures, and coma [54–56]. Cardiovascular manifestations include tachycardia, premature ventricular contractions, ST-segment abnormalities, hypotension, ventricular tachycardia, and ventricular fibrillation [53]. Acute renal failure may be related to hypotension, rhabdomyolysis, and the direct toxic effects of monofluoroacetate on kidney function [54]. Fatality is related to CNS and cardiovascular toxicities [53,55]. Laboratory abnormalities include significant metabolic acidosis and hypocalcemia from the fluoride, citrate, and fluoroacetate ions [53].

Management

General supportive measures are paramount and aimed at maintaining the airway, breathing, and circulation. Activated charcoal should be administered in all suspected oral exposures presenting within 1 to 2 hours after ingestion. Seizures should be treated with benzodiazepines, barbiturates, or propofol. Hypocalcemia and prolonged QTc intervals may require calcium and magnesium supplementation. Various treatments have been tested in animals [57]. The most useful agent appears to be glycercyl monoacetate, which provides excess acetate as a substrate for the TCA cycle [53,57]. The clinical use of glycercyl monoacetate remains unproven, however.
ALUMINUM AND ZINC PHOSPHIDES

Aluminum and zinc phosphides (AlP and Zn₃P₂) are highly toxic insecticides and rodenticides commonly used as solid fumigants and grain preservatives. They are considered to be ideal pesticides for grain preservation because of the simplicity of application, low cost, and high efficacy without grain contamination. Although highly restricted in the United States, aluminum phosphate is widely available and commonly used for home grain storage in Asia and the Middle East, often sold as “Rice Tablet.” Typically, each pellet contains 3 g of 56% aluminum phosphate. Aluminum phosphate has become one of the most common suicidal agents in rural India and parts of the Middle East. As little as 0.5 g can be fatal to an adult. Phosphides are widely used by grain freighters and have emerged as the major maritime occupational health hazard. Phosphine (PH₃) is slowly liberated when phosphides react with moisture in the environment.

Pharmacology

Phosphides react with water to form phosphine; the reaction is exothermic and it may be accelerated in the acidic environment of the stomach [58]. Phosphine is then readily absorbed in the stomach. Phosphine itself can also be absorbed through the lungs. There is limited information on the pharmacokinetics and metabolism of phosphine, although it is known to be partly eliminated through the lungs.

The exact mechanisms of toxicity have not been completely elucidated but likely multi-factorial. The most cited mechanism is related to non-competitive inhibition of cytochrome C oxidase (complex IV in the mitochondria) but this inhibition may be incomplete [59,60]. Other important mechanisms include the inhibition of catalase and peroxidase, causing increases in the production of superoxide dismutase and lipid peroxidation [59–61]. As a cellular toxin, phosphine has deleterious effects on multiple organ systems, particularly organs with high metabolic demands.

Clinical Toxicity

Inhalation of phosphine gas results in immediate eye and mucus membrane irritation and early onset of pulmonary symptoms [58]. Oral ingestion of phosphides causes profound GI symptoms, including nausea, vomiting, and abdominal pain [58]. In these instances, esophageal lesions, such as ulcers, perforations, and strictures, can occur and they
are typically associated with the ingestion of undiluted pellets [58]. The diagnosis may be suggested from a decaying fish odor released by substituted phosphines and diphosphines. Silver nitrate–impregnated paper blackens in the presence of phosphine in the gastric fluid [60]. Respiratory symptoms include cough, dyspnea, and chest tightness. Pulmonary edema and respiratory failure may be delayed for several hours after oral exposure to phosphides [62]. Hypotension and shock are expected within 6 hours in serious exposures. Fatalities are related to cardiovascular collapse from vasodilation and myocardial damage [60,63–65]. Cardiac hypokinesis and decreased left ventricular ejection fractions have been demonstrated by echocardiography [60]. Various electrocardiographic changes have been reported, including ST-segment elevation and depression, QRS prolongation, bundle-branch blocks, atrioventricular nodal blockade, and supraventricular and ventricular tachycardia [63–65]. CNS symptoms may include headache, drowsiness, paresthesia, and tremor, but encephalopathy is uncommon unless the patient is in shock [60]. Other manifestations include severe metabolic acidosis, hepatitis, and renal failure [60,66]. Mortality rates vary from 38% to 77% in suicidal ingestions.

Management

The patient should be immediately removed from the contaminated environment after the rescuer is adequately protected. Airway, breathing, and circulatory support are important in the immediate management. Even though there is no reported secondary toxicity to health care providers, the resuscitation area should be well ventilated. Activated charcoal should be mixed with sorbitol or magnesium citrate, rather than plain water, to reduce further liberation of phosphine in the GI tract. Other suggestions including careful lavage with sodium bicarbonate, antacid, potassium permanganate, or coconut oil but has not been adequately studied and cannot be recommended currently.

Cardiac monitoring and electrocardiography should be performed in suspected phosphine toxicity. Respiratory status should be monitored by continued clinical evaluation. Hypo- and hypermagnesemia have been reported with aluminum phosphide poisoning [63,64]. Chest radiography, pulse oximetry, and arterial blood gases should be obtained as clinically indicated.

There is no antidote for phosphine poisoning. The mainstay of therapy is supportive care and expected mortality is high. Although intravenous
magnesium therapy has been successful in treating various dysrhythmias, current studies results are contradictory [64,66]. Magnesium therapy in phosphide poisoning should be considered in patients with dysrhythmias or hypomagnesemia.
METHYL BROMIDE

Methyl bromide (Bromomethane, CH$_3$Br) is a colorless halogenated hydrocarbon gas primarily used as a fumigant for the control of nematodes, insects, rodents, fungi, and weeds. Methyl bromide was one of the most widely used pesticides in the United States and worldwide since the abandonment of chlordane and acrylonitrile as fumigants. Because methyl bromide causes ozone depletion in the stratosphere, the Montreal Protocol restricted its use in most developed countries since 2005. The United Nations proposed complete elimination of methyl bromide use worldwide by 2015. However, methyl bromide is still in use in many countries and in the United States at least until 2017 under critical use exemptions. Methyl bromide was particularly popular in the food industry because it is extremely effective, is able to diffuse into any empty spaces, and does not leave any residues after proper ventilation. Space fumigation of fruits and tobacco can be performed in an airtight (fumigation) chamber. For soil fumigation, methyl bromide can be applied underground and sealed with an overlying tent or polyethylene cover. For structural fumigation, gas-proof tarpaulins are applied over the structure before the application of methyl bromide. Methyl bromide is still used for the manufacture of chemicals such as aniline dyes. It has a musty and chloroform-like odor at high concentrations, but it is odorless at lower, but still very toxic, concentrations. Because methyl bromide is heavier than air, it is particularly dangerous in an enclosed environment. Inadvertent exposures from accidents or inadequate ventilation have caused significant toxicities and fatalities [67–69].

Pharmacology

Methyl bromide is primarily absorbed through the lungs. Cutaneous absorption is minimal. Methyl bromide easily penetrates and is retained in cloth, rubber, and leather. It is eliminated unchanged in the lungs, but a small proportion is metabolized to 5-methylcysteine and inorganic bromide; these are excreted in the urine [70]. Because of the low electronegativity of bromide, methyl bromide is a highly reactive chemical [68]. The mechanism of toxicity is probably related to the methylation of sulfhydryl groups in different intracellular enzymes and depletion of glutathione [68]. Methyl bromide can readily penetrate through lipid cell membranes [68]. Low concentrations of bromide may be detected in the serum after significant exposure to methyl bromide, but they do not correlate well with toxicity [67]. The symptoms of methyl bromide toxicity are distinctly different from those
of bromide salt toxicity [71].

Toxic effects primarily involve the central nervous and pulmonary systems [68]. Although exposures to concentrations of 2,000 ppm or greater may produce immediate CNS depression and respiratory failure, symptoms may be delayed for 1 to 6 hours or longer with exposure to lower concentrations. The current occupational exposure limits for methyl bromide are a California/Division of Occupational Safety and Health (Cal/OSHA) permissible exposure limit of 1 ppm with an 8-hour time weighted average and an American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value of 1 ppm [72].

Clinical Toxicity

The patients with mild toxicity may manifest dizziness, headache, confusion, weakness, nausea, vomiting, and dyspnea [68]. Initial or mild symptoms are frequently dismissed as viral symptoms. Skin irritation and burns commonly underlie clothes and rubber gloves, where the methyl bromide gas is trapped. After a significant exposure, the patient may present with tremor, myoclonus, and behavioral changes [67,73]. Severe toxicity may result in bronchitis, pulmonary edema, convulsions, and coma [67]. Fatality is related to pulmonary and CNS toxicities, although damage to different internal organs has been demonstrated [67,71]. Prolonged exposure to low concentrations of methyl bromide may cause subacute neurologic effects, such as headaches, confusion, behavioral changes, visual disturbance, and motor and sensory deficits [73–75]. Residual neurologic deficits may remain after significant acute or chronic exposure [71,75].

The essential laboratory studies for patients with methyl bromide intoxication are arterial blood gas or pulse oximetry monitoring. Chest radiography is useful in evaluating the patients with pulmonary symptoms. Serum bromide concentrations may suggest exposure, but do not correlate with the severity of exposure. Serum bromide concentrations varied from 4.0 to 65.6 mg per dL in methyl bromide fatalities [67,71,76]. When the serum bromide concentration is significantly elevated, an elevated chloride concentration may be observed with older chemistry analyzers [75].

Management

Treatment consists of supportive therapy, particularly of the airway, breathing, and circulation. Because methyl bromide is a gas, GI decontamination is not relevant. Clothing should be completely removed and the skin washed with soap and water to eliminate potential methyl bromide residues. Various compounds with sulphydryl groups, such as dimercaprol and N-acetylcysteine, have been suggested as potential
antidotes, but have not been demonstrated to be effective.
N,N-DIETHYL-m-TOLUAMIDE

N,N-Diethyl-m-toluamide (diethyltoluamide, or DEET) was initially synthesized in 1954 and marketed as an insect repellent. Currently, DEET is the most effective and one of the most widely used insect repellents. Use of DEET continues to increase with increasing public concern with arthropod-borne diseases, including Lyme disease, Dengue, and West Nile virus infections. The concentration of DEET in the various products varies from 5% to 100%.

Pharmacology

DEET is well absorbed through the skin, with 48% of the applied dose absorbed within 6 hours. The plasma concentration peaks 1 hour after dermal application [77]. DEET is primarily metabolized in the liver by several cytochrome P450 enzymes (CYPs), and 70% of the absorbed dose is excreted as metabolites within the first 24 hours. Another 10% to 15% is excreted unchanged in the urine [77,78]. DEET and its metabolites may accumulate in the fatty tissue, particularly after repeated applications.

The mechanism of DEET toxicity remains to be elucidated. Animals develop CNS symptoms similar to those reported in humans. Most reports of human poisoning involve children, likely because children absorb a higher ratio of DEET relative to their body weight. The initial theory suggested that the patients with ornithine-carbamoyltransferase deficiency might be particularly susceptible to DEET toxicity. However, this theory has not been substantiated.

Clinical Toxicity

Toxicity from DEET is primarily related to dermal exposures. Given the ubiquitous use of DEET, the overall reported adverse events are uncommon [78,79]. DEET may cause toxicity that is limited to skin irritation, contact dermatitis, skin necrosis, and urticaria [78]. Anaphylactic reactions have occasionally been reported with cutaneous application [80]. Manifestations of systemic poisoning vary from anxiety to behavioral changes, tremors, lethargy, ataxia, confusion, seizures, and coma [79,81,82]. Almost all of these case reports are related to application of concentrated DEET preparations or repeated application of lower concentration preparations [78,79]. Oral exposures to DEET are
uncommon, but can result in rapid onset of confusion, opisthotonus, and seizures even with small ingestions [83].

Management

Treatment is largely supportive. The patients with dermal exposure should have their skin washed with soap and water to prevent further systemic absorption. Activated charcoal may be considered for oral ingestion within 1 hour of presentation. Seizures may be treated with benzodiazepines, barbiturates, or propofol. Neurologic workup may be required in many patients. The symptoms of DEET toxicity should be distinguished from those of Reye syndrome. There is no antidote, and extracorporeal removal procedures are not helpful. Measures to prevent DEET toxicity may be the most important treatment. These include avoidance of concentrated DEET preparations. Products containing 20% to 30% DEET are adequate and safer than those with higher concentrations; concentrations of 10% or less are recommended for children. DEET should be applied only to exposed skin. An additional agent, such as permethrin, can be applied to clothing and may decrease the need of DEET. The skin should be washed with soap when the insect repellent is no longer required, and the number of repeat applications should be limited.
PENTACHLOROPHENOL

Pentachlorophenol was first synthesized in 1841 and first used as a pesticide in 1936. It is primarily used as a wood preservative, however. Unlike other types of pesticide toxicity in adults, pentachlorophenol poisoning usually results from occupational exposure. Occupational exposures to pentachlorophenol at wood-treating facilities frequently result from improper ventilation and inadequate engineering controls. Low-concentration, prolonged exposures to pentachlorophenol have been reported in log home residents from pentachlorophenol-treated wood. Epidemics of infant poisoning have resulted from diapers improperly laundered with pentachlorophenol-containing antimicrobial soaps.

Pharmacology

Pentachlorophenol can be absorbed by the respiratory, oral, and dermal routes, although pulmonary absorption is the most efficient route. The volume of distribution is 0.35 L per kg and the $pK_a$ is 5.0 [84]. Pentachlorophenol is primarily (74%) eliminated unchanged in the urine. A small proportion is oxidized to chlorohydroquinone, which is then eliminated in the urine. After a single oral exposure, the plasma half-life of pentachlorophenol is 27 to 35 hours [84]. Because of the low $pK_a$ and significant renal elimination, pentachlorophenol elimination can be enhanced by urinary alkalinization [85].

The mechanism of toxicity of pentachlorophenol is similar to that of dinitrophenol: these agents uncouple oxidative phosphorylation by altering the mitochondrial membrane and function as chemical ionophores to transport protons without linking them to ATP synthesis [86]. The shift in the proton electrochemical gradient resulted in potential energy dissipation as heat instead of ATP production, leading to altered thermohomeostasis and hyperthermia.

Clinical Toxicity

Acute exposure results in headache, diaphoresis, nausea, vomiting, weakness, abdominal pain, and fever. With severe toxicity, significant hyperthermia (up to 108°F or 42.2°C), coma, convulsions, cerebral edema, and cardiovascular collapse may occur [87,88]. Laboratory studies may reveal a respiratory alkalosis and metabolic acidosis from significant exposures. Chronic exposures to pentachlorophenol have been reported to cause aplastic anemia, intravascular hemolysis, and pancreatitis [89–91]. Chloracne has also been reported from these
exposures because of dioxin contamination in the product.

**Management**

Initial treatment includes oxygen supplementation, airway support, fluid resuscitation, and cardiac monitoring. Glucose should be monitored for hypoglycemia. Core temperature should be frequently monitored, and external cooling should be initiated immediately for significant hyperthermia. Seizures should be treated with benzodiazepines, barbiturates, or propofol to prevent further temperature increase and rhabdomyolysis. Fluid administration should be adequate to maintain a urine output of 1 to 2 mL per minute. Gastric decontamination (see Chapter 97) should be performed for oral exposure. The skin should be decontaminated with soap and water. Urinary alkalinization should be considered in patients with significant pentachlorophenol toxicity, although its clinical efficacy remains unproven [85].
Paraquat (1,1-dimethyl,4,4-bipyridyl dichloride) was developed in 1882 and for many years was used as an oxidation–reduction indicator. An electron donation to the compound forms a blue free radical; hence, paraquat was commonly called *methyl viologen*. The herbicidal properties of paraquat were discovered in 1955, and it was marketed as an herbicide in 1962. Today, paraquat is most commonly used as a nonselective contact herbicide in many countries. Paraquat can be applied safely when used according to the manufacturer’s guidelines. Typically, it is available as a 10% to 30% concentrated solution for agricultural use or as a 5% powder for domestic use. A new and safer formulation Inteon (contains an alginate that gels in acidic milieu, an emetic, and the osmotic cathartic magnesium sulfate) is designed to slow gastric absorption of paraquat, and increase vomiting and intestinal transit, but these effects have not been substantiated. Once diluted, paraquat has limited absorption through the skin [92] and by aerosolization into the respiratory system [93]. Paraquat is naturally inactivated in the soil and leaves little active residue in the environment. Despite its many desirable properties, however, the consequences of ingesting concentrated paraquat products are deadly. The median lethal dose of paraquat is 3 to 5 g in adults. As little as a mouthful (10 to 15 mL) of a 20% solution of paraquat is fatal. Paraquat ingestion is a prevalent method of suicide in countries in the Asia-Pacific region and the West Indies [1].

Pharmacology

Although oral exposure to paraquat is the most common route of toxicity, less than 5% of the ingested amount is actually absorbed. Any recent food ingestion may decrease the amount of systemic absorption. The peak plasma and lung concentration are reached within 1 to 2 hours and 5 to 7 hours after ingestion, respectively [94]. Plasma paraquat concentrations decline rapidly after peak absorption because of tissue distribution. Paraquat is particularly sequestered in the lungs, kidneys, and muscles [94,95]. The volume of distribution of paraquat is approximately 1.2 to 1.6 L per kg, but follows a multicompartment distribution model [95,96]. Paraquat is eliminated unchanged by the kidneys, with 90% of the ingested dose within 12 to 24 hours [95]. The terminal plasma half-life of
paraquat is 12 hours with normal renal function, but it may be as long as 120 hours as renal function deteriorates [95]. Dermal absorption of paraquat is minimal unless the exposure is prolonged with concentrated solutions [92]. Aerosolized paraquat particles have a diameter greater than 5 μm and do not reach the lower respiratory tree [93]. Concern about paraquat absorption from smoking marijuana is unfounded because much of the paraquat is pyrolyzed during the smoking process [97]. Paraquat toxicity from marijuana smoking has not been reported.

The primary organ of toxicity is the lung because of selective accumulation of paraquat. Paraquat is actively transported into type I and II alveolar cells through an existing transport system for endogenous polyamines. Paraquat and polyamines share a common structural property: they have two positively charged quaternary nitrogen atoms separated by a distance of 6 to 7 nm [98]. Diquat, another related herbicide with different structural features, is not selectively taken up and does not appear to cause pulmonary toxicity. Inside the cell, paraquat undergoes redox recycling, where a single-electron reduction into paraquat free radical by NADPH. This free radical reacts (oxidizes by) with oxygen to form superoxide free radicals and recycles back to react with NADPH. This reaction depletes NADPH. The superoxide free radicals deplete glutathione, cause lipid peroxidation and cellular apoptosis [99,100]. This mechanism of action is also responsible for the phytotoxic property of paraquat. There is also evidence for direct inhibition of electron chain transfers in mitochondria [99].

Clinical Toxicity

The onset and severity of poisoning are largely determined by the amount of exposure. The patients who ingest more than 40 mg per kg usually die within hours to a few days. These patients experience multiple organ failure, including acute lung injury, cerebral edema, myocardial necrosis, and hepatic and renal failure [99,100]. Death can be dramatic and may occur even before the development of significant chest radiographic abnormalities [99]. The patients who ingest 20 to 40 mg per kg of paraquat are most likely to die from pulmonary fibrosis, which progresses after a few days to a few weeks [99]. Ingestion of less than 20 mg per kg may lead to mild toxicity.

Paraquat is extremely corrosive to mucous membranes, and the patients frequently complain of pain in the mouth, throat, esophagus, and abdomen [99]. The absence of significant ulcerations in the esophagus or stomach within the first 24 hours of exposure may be a good prognostic indicator. The development of renal failure is a poor prognostic indicator [100]. This phenomenon cannot be fully explained by the decreased
elimination of paraquat in the body because most of the paraquat dose is eliminated within the first 24 hours, even in the setting of renal failure [94]. Conversely, renal failure may signify a large paraquat exposure. Almost all patients with renal failure from paraquat have significant pulmonary toxicity, but there are occasional reports of renal failure without significant pulmonary toxicity [101]. The prognosis for a patient with paraquat ingestion can be best determined by the measurement of plasma paraquat concentration and its relation to time of ingestion. The nomogram initially was presented by Proudfoot et al. [102] and subsequently refined by Hart et al. [103]. The severity index of paraquat poisoning (SIPP) can also be calculated based on the paraquat serum concentration in mg per L multiply the time of ingestion in hours. A SIPP of 10 to 50 predicts death from respiratory failure and greater than 50 predicts death from circulatory failure [104]. The availability of paraquat measurements depends on regional practice because this laboratory analysis is not routine. Sodium dithionite test is readily available can be applied to the urine or plasma for prognosis [105]. Although it is generally accepted that paraquat is not absorbed through the skin, it can be corrosive to the skin and nails. Occasionally, dermal absorption and systemic toxicity may occur from prolonged exposure or exposure to concentrated products [92].

Management

It is critical to prevent systemic absorption of paraquat. Once ingested, it is rapidly absorbed and sequestered, frequently leading to death. GI decontamination should be performed in any suspected paraquat ingestion. Orogastric lavage should be performed if the ingestion is within 1 to 2 hours and if the patient did not have any vomiting. Fuller earth (1 to 2 g per kg) or activated charcoal should be administered with a cathartic agent as soon as possible to bind any residual paraquat in the GI tract [106]. Multiple doses of oral adsorbents should be continued until there is evidence of adsorbent in the stool. This is done to prevent desorption of the paraquat. Any dermal exposure should be thoroughly washed with soap and water. Plasma and urine analytical methods to detect paraquat are useful to confirm the diagnosis and assess the prognosis. A rapid qualitative screen for paraquat exposure may be performed by the addition of sodium dithionite to urine under alkaline condition. A change in color to blue confirms exposure to paraquat [99]. Furthermore, prognosis may be predicted by the degree of color change: dark blue for poor prognosis and light blue for moderate-to-severe poisoning [105].

The treatment of paraquat toxicity consists of supportive care, particularly for circulatory monitoring and support. Palliative care should
be considered and discussed with the patients and their family in those determined to have poor prognosis. Oxygen supplementation should be avoided because it may increase the formation of paraquat free radicals and worsen pulmonary toxicity [99,107]. Supplemental oxygen should be administered only when it is necessary and should maintained pulse oximetry no higher than 90% saturation, even though the prognosis is grave in this group of the patients.

Experimental therapies for paraquat toxicity have been formulated using various strategies. Forced diuresis does not have significant effects on paraquat elimination. Hemodialysis and charcoal hemoperfusion are similar to endogenous renal clearance of paraquat but may increase elimination in those with renal dysfunction. In an animal model, the institution of charcoal hemoperfusion within 2 hours after paraquat ingestion decreased the fatality rate, and institution of hemoperfusion 2 hours after paraquat administration did not alter the paraquat concentration in the central compartment [96]. Clinically, hemodialysis, charcoal hemoperfusion, and continuous arteriovenous hemofiltration have not altered mortality rates but may be necessary in patients with renal failure. There are significant limitations in applying extracorporeal procedures. Because of the relatively large volume of distribution, rapid sequestration into tissue compartments, and good endogenous clearance, extracorporeal removal must be performed during peak absorption (within 2 hours after ingestion) to significantly decrease the paraquat load in the central compartments [96]. Because most patients present a number of hours after ingestion and the logistics of extracorporeal removal typically translate into an additional 1- to 2-hour delay, the amount of paraquat removed in most instances is insignificant.

Immunotherapy with monoclonal antibody fragments (Fab, Fv) against paraquat or against the active transport mechanism in the cells is intriguing [108]. More research is required to assess the value of this therapy, however. Various agents such as putrescine and spermidine and \( \beta \)-adrenergic receptor blockers have been demonstrated to prevent active transport of paraquat into lung tissues but failed to provide any benefits in vivo [99].

Various antioxidants and free radical scavengers, such as vitamins C and E, deferoxamine, superoxide dismutase, clofibrate, selenium, glutathione peroxide, and \( N \)-acetylcysteine, have been tested against paraquat toxicity. To date, there has been no or insignificant improvement in animal models [99]. A recent study using inhaled nitric oxide in rats demonstrated benefits in preventing pulmonary injuries and
survival [99]. The most controversial treatment is related to the use of pulse-dose methylprednisolone and cyclophosphamide therapy, to limit acute inflammatory response. Corticosteroid also activates p-glycoprotein to increase efflux and decrease the intracellular concentration of paraquat [109]. Several studies have demonstrated increased patient survival with corticosteroids and cyclophosphamide therapy (Table 120.4) [109–111].

Meta-analysis of the three prospective randomized controlled studies with the use of methylprednisolone and cyclophosphamide in 164 patients appears to decrease mortality (RR 0.72, 95% CI 0.59 to 0.89) in patients with moderate-to-severe poisoning from ingested paraquat [112]. All patients received GI decontamination and two sessions of charcoal hemoperfusion within 24 hours of hospitalization, which were completed prior to the initiation of the pulse-dose therapy. Cyclophosphamide can cause a transient leukopenia (WBC < 3,000 per μL) in patients treated with the protocol [110]. The largest prospective randomized controlled study of 298 patients, was terminated early because the sale of paraquat was banned in Sri Lanka and it demonstrated no difference in mortality, 71% in the placebo group versus 68% in the treatment group [113]. These results have only been published in abstract format so far. The effectiveness of methylprednisolone and cyclophosphamide will be further determined by the publication of these results and the meta-analysis of all prospective controlled study data.

Other agents that may alter pulmonary fibrosis, such as colchicine, nonsteroidal anti-inflammatory agents, collagen synthesis inhibitors, and angiotensin-converting enzyme inhibitors, also require further study. Lysine and sodium acetylsalicylates modulate inflammation and apoptosis, chelate paraquat, may have potential effects in animals but require further investigation. Niacin, which increases nicotinamide adenine dinucleotide phosphate synthesis, has some protective effects in rats, but it is unclear if it is applicable to human toxicity [99].

Early lung transplantation has been unsuccessful because of toxicity to the transplanted lung when paraquat is redistributed from tissue stores [114,115]. A successful case of lung transplantation was performed in a patient 44 days after paraquat poisoning, however [116]. Extracorporeal membrane oxygenation should be investigated in the future as a potential bridge to delayed pulmonary transplant [117].
Diquat (1,1′-ethylene-2,2′-dipyridylium ion) is a contact herbicide with action and structure similar to that of paraquat. Diquat and paraquat liberate hydrogen peroxide and oxygen free radicals, resulting in toxicity to plants and animals [118]. The use of diquat is more limited and hence results in fewer intoxications than paraquat. Diquat is often formulated with paraquat.

Pharmacology

The kinetics of diquat are unknown in humans. In animal models, less than 10% of the oral dose is absorbed. More than 90% of the absorbed dose is eliminated unchanged by the kidneys [119]. There are no known metabolites of diquat.

Although diquat is less toxic than paraquat, human fatalities have been reported with ingestion of 20 to 50 mL of a 20% solution [120]. Similar to paraquat, diquat causes multiple organ damage. Diquat normally spares the pulmonary system, however [120]. This is because diquat is not actively transported to and concentrated in the alveolar cells of the lungs [98].

Clinical Toxicity

Symptoms of diquat toxicity may be delayed several hours to 2 days [120]. Vomiting, abdominal pain, GI tract erosions, and paralytic ileus are common manifestations of toxicity [120,121]. Acute renal failure may be related to hypovolemia and the direct toxic effects. The effects of diquat on the CNS may result in lethargy, seizures, and coma [121]. Brain-stem infarctions may be specific to diquat toxicity. All patients who die have significant CNS manifestations before cardiovascular collapse [121,122]. Topical exposure to diquat can occasionally result in severe skin burn [123].

Management

Treatment is largely supportive and similar to that for paraquat. Gastric lavage should be performed for any potential diquat ingestion within 1 hour if the patient has not vomited. Fuller’s earth or activated charcoal
should be administered as soon as possible. Hemodialysis or hemoperfusion has not been demonstrated to be effective for the treatment of diquat toxicity but may be necessary in patients with renal failure [122,124].
CHLOROPHENOXY HERBICIDES

Chlorophenoxy herbicides are used to control broad-leaf weeds and woody plants. They exert their effects by mimicking the action of auxins (plant growth hormones) and cause overstimulation of plant growth. Numerous derivatives are available for agricultural and domestic use [125]. The most commonly used agents include 2,4-dichlorophenoxyacetic acid (2,4-D), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), and 2-methyl-4-chlorophenoxypropionic acid. Many preparations contain more than one chlorophenoxy herbicide or other types of herbicides. Despite extensive use of these agents, fatality and significant toxicity are limited. The chlorophenoxy herbicides are notorious because of dioxin contamination in Agent Orange, a 1-to-1 mixture of 2,4-D and 2,4,5-T used extensively in the Vietnam War, so named for the color of the drums used to store it. Agent Orange contained dioxin (2,3,7,9-tetrachlorodibenzodioxin), a contaminant in the synthesis of chlorophenoxy compounds and a potent teratogen in animals [126,127].

Pharmacology

In general, chlorophenoxy herbicides are well absorbed orally. Inhalation absorption from occupational exposure can be significant with associated systemic toxicity. They have small volumes of distribution, large renal excretion, and a low pKₐ [128]. 2,4-D has a volume of distribution of 0.1 to 0.3 L per kg and a pKₐ of 2.6 to 3.5 [149]. Oral doses of 5 mg per kg in human volunteers produce no ill effects. The peak serum concentration is achieved within 4 to 12 hours [129], 80% of the absorbed dose is eliminated unchanged in the urine, and 13% is eliminated as acid-labile conjugates. The plasma half-life is 18 to 40 hours and varies with urine pH; it may range from 4 to 220 hours [130]. The volume of distribution of 2,4,5-T is 6.1 L per kg. It is exclusively excreted unchanged in the urine, and the plasma half-life is 11 to 23 hours [131].

Various mechanisms of toxicity in humans are postulated. Uncoupling of oxidative phosphorylation has been demonstrated in vitro and may be responsible for a mild heat exhaustion syndrome [132,133]. Chlorophenoxy herbicides can interfere with the TCA cycle and cellular metabolism by forming analogues with acetyl coenzyme A [131,132]. There may be other direct toxic effects on skeletal muscles and peripheral nerves [134].
Clinical Toxicity

GI symptoms are common, and the patients frequently experience nausea, vomiting, diarrhea, and abdominal pain [135,136]. Ulcerations may occur at the mouth and pharynx, but are uncommon elsewhere in the GI tract [132]. A mild heat exhaustion syndrome consisting of fever, diaphoresis, and hyperventilation can be seen [135]. The CNS is particularly affected, and the patients may present with confusion, lethargy, convulsions, and coma [135,137]. Prolonged coma (up to 4 days) has been reported with 2,4-D toxicity [138]. Myotonia, rhabdomyolysis, and chronic muscle weakness are also reported [136]. Renal complications may result from rhabdomyolysis and myoglobinuria [139]. Hypocalcemia may occasionally be seen as a result of rhabdomyolysis and hyperphosphatemia [137]. Fatality is uncommon, and the cause of death remains unclear [130,140,141]. Chlorophenoxy assays are not widely available and do not correlate well with clinical toxicity, even though a total chlorophenoxy herbicide concentration of greater than 0.5 g per L was purported to be associated with severe toxicity [133,134].

Management

Gastric decontamination with lavage may be considered within 1 hour of ingestion in patients without vomiting. Activated charcoal should be administered. Skin should be decontaminated with soap and water. Basic supportive therapies include the maintenance of good urine output (1 to 2 mL/kg/h) with fluid resuscitation and external cooling for hyperthermia. Because of the low pK_a and renal elimination of chlorophenoxy herbicides, urinary alkalization can significantly enhance renal excretion and decrease the plasma half-life of various chlorophenoxy herbicides [135]. Thus, it should be initiated in patients with significant toxicity by using a sodium bicarbonate infusion to titrate the urinary pH to 7.50 to 8.0. The patient’s fluid status should be closely monitored because renal dysfunction may develop from chlorophenoxy herbicide toxicity. Although the utility of extracorporeal elimination of chlorophenoxy herbicides in poisoned patients has not been studied, hemodialysis may be useful for 2,4-D because of its small volume of distribution. In severe cases and in patients with renal insufficiency, hemodialysis may be preferred because it produces good herbicide clearance, without the need for pH manipulation and administration of large amount of intravenous fluid.
CHLORATE SALTS

Chlorate salts (sodium chlorate \([\text{NaClO}_3]\) and potassium chlorate \([\text{KClO}_3]\)) are nonspecific herbicides. They are also used in the manufacture of explosives, dyestuffs, tanning agents, and matches.

Pharmacology

Chlorates are strong oxidizing agents that result in methemoglobinemia and hemolysis. They have direct toxic effects on the kidneys and indirect nephrotoxicity from hemoglobinuria. Because chlorates are primarily eliminated by the kidneys, nephrotoxicity further enhances their toxicity. The acute lethal dose is 25 to 35 g [142].

Clinical Toxicity

GI symptoms are prominent within hours after an acute exposure and include nausea, vomiting, diarrhea, and abdominal pain [142–144]. Methemoglobinemia and hemolytic anemia result from the oxidizing effects. Both entities may result in a significantly decreased oxygen-carrying capacity and cellular hypoxia [143,145]. Cyanosis may be evident with significant methemoglobinemia. Acute renal failure typically develops within 48 hours after exposure [144,146]. Significant hyperkalemia from hemolysis is another potential fatal complication.

Management

Initial supportive care should be directed at the airway, breathing, and maintenance of circulation. Continuous cardiac monitoring should be initiated. Gastric decontamination should be performed within 2 hours after ingestion unless the patient already has significant vomiting. Laboratory studies should include hemoglobin, serum electrolytes, blood urea nitrogen, creatinine, and methemoglobin concentrations. Electrocardiogram and arterial blood gas should be obtained as clinically indicated. Intravenous or oral sodium thiosulfate (2 to 5 g in 200 mL of 5% sodium bicarbonate solution) has been advocated to inactivate the chlorate ion, but its efficacy has not been clinically proven [147]. Methylene blue should be administered for clinically significant
methemoglobinemia, but it may not be effective in the setting of significant hemolysis because intact intracellular enzymes are required for its therapeutic effect [148]. Methylene blue is indicated in patients with a methemoglobin concentration of more than 20% or at a lower value in symptomatic patients with anemia. The initial dose is 1 to 2 mg per kg administered intravenously over 5 minutes and a response is anticipated within 30 minutes. Subsequent doses of methylene blue can be administered if there is an initial success, but it is withheld if no response is observed. Exchange transfusion may be required for refractory methemoglobinemia or significant hemolysis. Hemodialysis can remove chlorates and is recommended for patients with associated renal dysfunction [142,147].

Phencyclidine and Hallucinogen Poisoning

JENNIE A. BUCHANAN • LUKE YIP

PHENCYCLIDINE

Phencyclidine (phenyl-cyclohexyl-piperidine, or PCP) is a dissociative anesthetic chemically related to ketamine. PCP is a synthetic compound developed in the 1950s as a general anesthetic (Sernyl). It was associated with an unacceptably high incidence of postoperative hallucinations, delirium, and mania. In 1967, PCP was reintroduced and marketed as a veterinary anesthetic (Sernylan). Currently, PCP is a Schedule II substance in the United States; ketamine is a Schedule III agent. As an illicit drug, PCP is available as a white crystalline powder (angel dust), tablet (PeaCe Pill), crystals, and liquid (whack); it can be snorted, smoked, ingested, or injected. Tables 121.1 and 121.2 display some of the common slang, or street names, for both PCP and ketamine.

Pharmacology

There are two forms of PCP, acid and base. Both are odorless, nonvolatile, and sold as “angel dust,” and may be ingested or injected. PCP acid is a white crystalline substance sold as or incorporated into tablets. It deteriorates when heated and is not suitable for smoking. PCP base is a grayish-white amorphous powder that can be smoked after incorporation into marijuana (e.g., supergrass, superweed) or tobacco (e.g., clickers, primos) cigarettes. More often, the base is dissolved in a liquid hydrocarbon and applied to the wrapper of a tobacco cigarette. The ether-like or formaldehyde odor surrounding some patients who have used PCP is from the volatile hydrocarbon used to dissolve PCP base.

Several analogs of PCP are occasionally used as street drugs (Table 121.3). Their pharmacologic actions are similar to those of PCP and cannot be clinically distinguished. In addition, street PCP samples may be contaminated with 1-piperidinocyclohexane-carbonitrile, a precursor of PCP that is more potent than PCP and capable of generating cyanide, although the clinical significance of this is unknown.

PCP has multiple mechanisms of action (Table 121.4), which helps to explain the varied signs and symptoms associated with PCP intoxication.
It is well absorbed from the gastrointestinal (GI) and respiratory tracts. PCP is a weak base ($pK_a$ 8.5), has a volume of distribution 6.2 L per kg, and is extensively protein-bound (65%) [12]. PCP concentrates in the brain, lungs, adipose tissue, and liver. The average serum half-life in controlled studies is 17 hours. PCP is metabolized by the liver and excreted predominantly as inactive compounds. Small amounts of PCP are excreted in perspiration, saliva, and gastric juice. PCP has been detected in umbilical and infant blood, amniotic fluid, and breast milk.

### Clinical Toxicity

Drinking PCP, intravenous PCP, or swallowing remnants of PCP-soaked cigarettes have resulted in severe intoxication within 1 hour. Clinical experience with PCP intoxication is derived from case reports and clinical series [13–20]. The characteristics of PCP intoxication are nystagmus and hypertension. Nystagmus may be horizontal, vertical, or rotary. The patients may have systolic or diastolic hypertension. Hypertension
usually resolves within 4 hours, but a significant number of patients may remain hypertensive for more than 24 hours.

Tachycardia is common. However, heart rates greater than 120 per minute are unusual. Hypothermia (<36.7°C), hyperthermia (>38.9°C), respiratory compromise, tachypnea, hypotension, and cardiac arrest have been reported.

The patients may present with delirium or normal sensorium. Lethargy, stupor, and unconsciousness are uncommon presentations. The most common behavioral effects are violent and agitated behavior, which may predispose patients to traumatic injuries. The patients may exhibit bizarre behaviors such as driving less than 10 mph on the freeway, “playing bumper cars” on the freeway, sleeping on top of cars that are blocking traffic, lying down in a busy street, and wandering or acting wildly in public. Approximately 20% of PCP users report hallucinations or delusions. The visual hallucinations are typically concrete and realistic (e.g., blue fish). The patients may appear mute or have a “blank stare” appearance.

The most common neuromuscular finding is rigidity of all extremities. It is often associated with jerky or thrashing movements, tremors, or twitching. Other musculoskeletal disturbances include oculogyric crisis, trismus, facial grimacing, circumoral muscle twitching, lip smacking or chewing movements, torticollis, tongue spasms, opisthotonos, and catalepsy. The patients may exhibit self-limited slow, writhing movements of the extremities or body. Athetosis and muscle stiffness may simultaneously appear. Intermittent athetoid movements may last for more than 10 hours. Rhabdomyolysis may occur, even in calm-appearing patients. Grand mal seizures and status epilepticus are uncommon.

The major autonomic effects are profuse diaphoresis, copious oral or pulmonary secretions, and urinary retention. Bronchospasm has been reported in patients who smoked or sniffed or snorted PCP. Pupillary size is usually normal, but miosis or mydriasis has been described.

Clinically, acute PCP intoxication can be divided into major and minor clinical syndromes [19]. Major syndromes, representing moderate-to-severe PCP intoxication, are delirium, toxic psychosis, catatonic syndrome, and coma. They may include any of the previously discussed effects. Minor syndromes are lethargy or stupor, bizarre behavior, violent behavior, agitation, and euphoria. They represent mild PCP intoxication, and complications are rare.

Delirium is the most common presentation of PCP intoxication. The patients may be found wandering in traffic or appear intoxicated with ethanol. The patients may exhibit slurred, bizarre, or repetitive speech; ataxia; disorientation; confusion; poor judgment; inappropriate affect; amnesia of recent events; bizarre behavior; agitation; and violence. The
duration of this syndrome often lasts for a few hours and rarely lasts more than 3 days, but has been reported to persist for 1 to 3 weeks.

Psychosis may appear in some patients following PCP use and may last for days or weeks despite abstinence; typically symptoms become more severe during the first few days of its course. PCP psychosis may be defined as a schizophreniform psychosis. Characteristically, there is autistic and delusional thinking, commonly including global paranoia, delusions of superhuman strength and invulnerability, as well as delusions of persecution and grandiosity. Affect is generally blunted, with periods of suspiciousness often alternating with extreme anger or terror. These patients are ambivalent and their behavior is unpredictable even toward their friends and relatives. They may be reluctantly cooperative one minute and violently aggressive the next. Some carry lethal weapons to protect themselves from their imagined persecutors. Bystanders have been unexpectedly, furiously, and unremittingly attacked without provocation. Hallucinations may be auditory or visual, or both, and may involve seeing brilliantly colored objects, but objects are not distorted and there are no kaleidoscopic effects. The patients may be preoccupied with religious thoughts or have religious delusions. It is common for patients to have pressured speech, scream, or make animal sounds. In the initial phase of PCP psychosis, the patients may be an immediate danger to themselves on the basis of impaired judgment and being unable to care for themselves. Their violent and threatening behavior may provoke lethal countermeasures by those around them. These patients may also be a danger to others because of their misperceptions, paranoia, and hostility, compounded by their confusion, tendency towards violence, and the unpredictability of behavior. This initial phase will gradually transition to a phase characterized by intermittent periods of gross paranoia, agitation, terror, and hyperactivity alternating with quiet paranoid watchfulness over the course of a week. Affect may remain constricted. The patients may explode in an unexpected flurry of violence when inappropriate demands are not immediately met. A third phase begins on an average of 10th day of hospitalization, and is characterized by rapid reintegration of premorbid personality, development of insight into the events leading to the hospitalization. There is often amnesia from the early events of the psychosis.

The catatonic syndrome manifests primarily as a combination of signs: posturing, catalepsy, rigidity, mutism, staring, negativism, nudism, impulsiveness, agitation, violence, and stupor. Stereotypies, mannerisms, grimacing, and verbigeration may also be present. The patients are
typically mute, staring blankly, motionless, stiff, standing with extremities or head in bizarre positions, and unresponsive to noxious stimuli. Most catatonic syndromes usually do not persist for more than 24 hours (range 2 to 6 days), and most patients recover within 4 to 6 hours. The patients may emerge from catatonic syndrome with agitation or combativeness, delirium, lethargy, psychosis, bizarre behavior, or normal sensorium.

Violent, agitated, and euphoric patients typically have a clear sensorium. The patients with euphoria may report a sense of “well being” or feeling “spaced out,” “freaked out,” or “tingling all over.” The patients with delirium and violent or bizarre behavior may subsequently lapse into coma. Coma may also occur abruptly and may last up to 6 days. The patients emerging from coma may exhibit delirium, catatonic syndrome, toxic psychosis, stupor, agitation, violence, bizarre behavior, or normal sensorium. The duration of the emergent phenomenon is variable.

Neonatal jitteriness, hypertonicity, and vomiting have been associated with maternal PCP use. Chronic PCP intoxication has not been described, and there is no documentation of PCP flashbacks. Common clinical effects are summarized in Table 121.5

**Diagnostic Evaluation**

PCP intoxication is a clinical diagnosis. It is based on a history of possible PCP exposure associated with clinical findings consistent with PCP intoxication and the exclusion of other neuropsychiatric or behavioral disorders. Drug history should include type of product, method of use, time of exposure, circumstances surrounding intoxication, and description of effects witnessed by others or experienced by the patient. Particular attention should be paid to abnormal behavior that may have resulted in occult trauma (e.g., jumps or falls).
The physical examination should focus on vital signs, sensorium, behavior, and musculoskeletal, autonomic, and neurologic findings. A thorough examination should be performed to exclude occult trauma. Explosions in clandestine laboratories may have consequences of smoke or chemical inhalation, thermal or chemical burns, and blunt or penetrating trauma.

Laboratory tests should include complete blood cell count, serum electrolytes, blood urea nitrogen, creatinine, glucose, creatinine phosphokinase (CPK), liver function tests, and urine analysis to include myoglobin. Common abnormal test results associated with PCP intoxication include hypoglycemia, elevated white blood cell count, serum CPK, liver function tests, and uric acid. Chest radiograph, electrocardiogram, arterial blood gas, computed tomography of the head, and lumbar puncture should be obtained as clinically indicated.

Serum or urine PCP levels can confirm the diagnosis of PCP intoxication, but neither contributes to patient management nor correlates with severity of intoxication. Rapid urine qualitative drug screens that detect PCP should be interpreted with caution. Diphenhyramine, ketamine, lamotrigine, thioridazine, tramadol, ibuprofen, imipramine, meperidine, mesoridazine, venlafaxine, and o-desmethylvenlafaxine may cause false-positive PCP results on urine qualitative drug screens. Diphenhydramine may interfere with PCP determination by gas–liquid chromatography.

Management

The immediate management is to assess and treat acute threats to the airway, breathing, and circulation. Close monitoring of the patient in a quiet area with limited stimuli may reduce the need for physical restraint or sedation and provide a safe environment for the patient, attending staff, and other patients. Routine gastric decontamination is not recommended.

The patients with major PCP intoxication syndrome or complicated minor PCP intoxication syndrome should be managed in an intensive care unit. These patients should receive supplemental oxygen, secure vascular access, and have their vital signs and cardiac rhythm continuously monitored. A core temperature should be obtained for all patients.

Hemodynamic effects of PCP usually do not require specific treatment. Abnormal vital signs should be managed in the context of the overall clinical status of the patient. Mild sinus tachycardia or hypertension not associated with psychomotor agitation or evidence of end organ damage usually does not require pharmacologic treatment. Treatment of psychomotor agitation using benzodiazepine sedation often results in
improvement or resolution of sinus tachycardia and hypertension. Persistent significant hypertension despite resolution of psychomotor agitation, or if there is evidence of end organ damage, should be treated with intravenous nitroprusside or nitroglycerin titrated to effect. The use of β-adrenergic antagonists to treat drugs of abuse-induced tachycardia or hypertension is not routinely recommended and may have deleterious effects (e.g., unopposed α-adrenergic effects).

The patients with hypotension should receive fluid resuscitation while alternative causes are being investigated (e.g., occult trauma). Persistent hypotension refractory to fluids necessitates a vasopressor such as norepinephrine or epinephrine. Pulmonary artery catheter hemodynamic monitoring may provide important data to guide pharmacologic intervention. Cardiac dysrhythmias should be managed according to current Advanced Cardiac Life Support guidelines.

Core temperature approaching or exceeding 104°F (40°C) is immediately life-threatening and warrants aggressive management. Rapid-sequence induction (sedation and paralysis), intubation, and ventilation may be required. Completely undress the patient, begin continuous monitoring of the patient’s core temperature, and initiate active cooling measures. Active cooling should be terminated when the patient’s core temperature approaches 101°F (38.3°C). Antipyretics (e.g., acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs) are not useful, and there is no good evidence that dantrolene, bromocriptine, or amantadine enhances the cooling process in patients with life-threatening hyperthermia.

The initial management of a patient with altered mental status should include assessment and treatment of all readily reversible causes such as hypoxia, hypoglycemia, opioid toxicity, and thiamine deficiency. Imaging studies of the head should be performed for patients with persistent altered mental status, followed by lumbar puncture as clinically indicated. Antibiotic and antiviral medications should be administered as soon as the diagnosis of meningitis or encephalitis is entertained.

Mild psychomotor agitation usually does not require active intervention. However, aggressive treatment of PCP psychosis is critical to prevent injury to the patient or others. The patient should be isolated in a secured bare seclusion room with frequent, but unobtrusive observation; seclusion safeguards staff and other patients, calms the patient through reduction of stimuli. Haloperidol and chlorpromazine (after excluding acute PCP and anticholinergic toxicity) have been reported to be safe and effective treatment of PCP psychosis [17,21], and
benzodiazepines may be preferred for patients because they lack anticholinergic and extrapyramidal side effects, do not lower seizure threshold, and have not been associated with hyperthermia or neuroleptic malignant syndrome. The dose of benzodiazepine should be titrated to achieve moderate sedation to obviate physical restraints. Occasionally, large doses (e.g., >100 mg of diazepam) may be necessary to achieve safe gentle sedation. The patient’s ability to protect the airway should be carefully monitored. Intubation and ventilation are rarely necessary.

Seizures should be treated with intravenous benzodiazepines. Cumulative high-dose benzodiazepines may be required. If seizure activity is not rapidly controlled, intravenous propofol or phenobarbital is indicated. Seizures refractory to sedative hypnotic drugs should be managed with nondepolarizing neuromuscular blockade and general anesthesia, along with continuous electroencephalogram monitoring.

Fluid management should address electrolyte and acid–base abnormalities. Management of rhabdomyolysis should include treatment of psychomotor agitation and generous intravenous crystalloid fluids to maintain urine output of at least 2 to 3 mL/kg/h to maximize glomerular filtration rate. Because serum myoglobin levels are not usually rapidly available, serum CPK may be monitored noting that the clinically important myoglobin serum peak may precede the CPK peak by several hours. Care should be taken to prevent dependent muscle injury.

Although urinary acidification can increase renal PCP excretion, the risks associated with urinary acidification outweigh potential benefits. Hemodialysis is not indicated for enhanced drug elimination but may be necessary in patients with acute renal failure.

The patients with suicidal ideation or persistent psychosis should be referred to the psychiatric service.
HALLUCINOGENS

The term “hallucinogen” has come to describe lysergic acid (LSD, or “acid”), and related compounds based on their reported hallucinogenic effect. However, it has been argued that common recreational doses rarely produce frank hallucinations. Other designations for this class of drugs include psychedelics, psychotomimetics, and entheogens. Hallucinogens are primarily composed of synthetic indolamines (derivatives of tryptamine), phenethylamines (derivatives of amphetamine, see Chapter 100), and botanical products. The psychedelic experience may precipitate homicidal acts, self-destructive behavior, accidental injuries, and acute or chronic psychosis. Physiologic effects vary from mild flushing to life-threatening alterations in vital signs, coma, seizures, and coagulopathy.

Pharmacology

Synthetic hallucinogens are sold as liquid, powder, tablets, capsules, microdots (dried drug residue) on printed paper, liquid-impregnated blotter paper, and as windowpanes (translucent 3 × 3 mm gelatin squares).

The routes of administration are oral, intranasal, sublingual, conjunctival, smoking, or intravenous injection. Blotter paper is chewed and swallowed, whereas microdot paper is usually licked. Windowpanes are usually placed under the tongue or in the conjunctival sac, and may also be swallowed.

The mechanisms of action for hallucinogens are presumed to involve various neurotransmitters in the central nervous system. Hallucinogenic effects on thought and perception appear to primarily involve serotonin (5-hydroxytryptamine, or 5HT) neurotransmission. Serotonin modulates psychologic and physiologic processes such as affect, mood, personality, sexual activity, appetite, motor function, pain perception, sleep induction, and temperature regulation. Tryptamine, derivatives from the tryptophan metabolism, has been shown to be a sigma-1 receptor agonist and their hallucinogenic effects are believed to be primarily mediated by the 5-HT2A receptor [22].

Hallucinogens are readily absorbed from the GI tract, metabolized by the liver, and excreted predominately as pharmacologically inactive compounds. The clinical effects produced by different agents are very similar.

LSD, the most widely abused tryptamine derivative, was originally synthesized from an ergot alkaloid. The structural similarity between
Tryptamines and serotonin engenders significant activity at serotonergic receptors across this chemical class. LSD has the highest affinity for the 5-HT<sub>2A</sub> receptor and the highest potency for hallucinogenic effects in humans [23]. Experimentally, the stimulus effects of LSD are completely antagonistic by acting as a highly selective 5-HT<sub>2A</sub> antagonist. The usual street form is a 1 cm<sup>2</sup> piece of blotter paper (tabs). At doses of 100 μg, LSD produces perceptual distortions and hallucinations.

Morning glory (<i>Ipomoea</i> and <i>Rivea</i> genera) seeds contain LSD derivatives that are one-tenth as potent as LSD. Users report that to achieve the desired hallucinogenic effect requires ingestion of 200 to 300 macerated seeds.

Psilocybin and psilocin are tryptamine derivatives found in <i>Psilocybe</i> and other hallucinogenic fungi (magic mushrooms). It is usually sold in the form of dried mushroom, capsules, or paper packets of brown powder. Pure psilocybin is available in capsules of white powder. The effective psilocybin dose is 5 to 15 mg, which is equivalent to ingestion of one to five large mushrooms. However, the clinical effects are dependent on a number of factors, including dose, method of preparation, and individual patient factors.

The toads of the genus <i>Bufo</i> secrete venom from their parotid glands onto their skin. This venom contains bufodienolides, which is a mixture of purported hallucinogenic tryptamine derivatives (e.g., 5-hydroxy-<i>N</i>,<i>N</i>-dimethyltryptamine, 5-OH-DMT, also known as bufotenine) and cardioactive compounds (e.g., bufogenin and bufotoxin); see Chapter 100 [24]. <i>Bufoalvarius</i> possesses an unusual enzyme, <i>O</i>-methyl transferase that converts bufotenine to a potent hallucinogen 5-methoxy-<i>N</i>,<i>N</i>-dimethyltryptamine (5-MeO-DMT). 5-OH-DMT is reported to be a constituent of hallucinogenic snuffs from northwest South America, derived from the leguminaceous tree, <i>Anadenanthera peregrine</i>. 5-MeO-DMT accounts for much of the psychoactivity of South American snuffs derived from <i>Anadenantheraperegrina</i> as well as those derived from species of <i>Virola</i>, a genus of trees in the nutmeg family. Hence, toad licking has been popularized by the belief that hallucinogenic effects may be achieved by licking the skin of live toads.

Dimethyltryptamine (DMT), a tryptamine derivative, is an endogenous hallucinogen in some plant species (e.g., <i>Virolacalophylla</i>, <i>Phalarisaquatica</i>, <i>Acacia maidenii</i>, <i>Acacia phlebophylla</i> and <i>Acacia obtusifolia</i>) and is a trace amine that is endogenously synthesized from tryptophan in mammals. DMT is rapidly and extensively metabolized to
3-indoleacetic acid by MAO-A, which may explain the reported lack of psychoactive effects following DMT ingestion and its significant psychotropic activity when smoked, injected, or insufflated [22]. However, the psychoactive activity of DMT is preserved when ingested in combination with a MAOI (e.g., “ayahuasca,” a DMT, and \( \beta \)-carboline plant decoction). Street DMT is available as a liquid or yellow-tan powder that it is sprinkled on tobacco, marijuana, or parsley and smoked. Smoking is the preferred route of exposure, and is claimed to produce potent psychospiritual effects.

Mescaline, another amphetamine congener, is the psychedelic constituent of peyote (North American dumping cactus, \textit{Lophophora williamsii}) and other cacti. Small segments of the crown of the cactus, known as “buttons” or “moons,” may be swallowed whole or chopped into small pieces. Ground peyote may be smoked. The hallucinogenic dose of mescaline is approximately 300 mg, corresponding to 6 to 12 buttons.

**Clinical Toxicity**

Acute psychedelic effects (trip or tripping) are characterized by changes in sensory perception. They include euphoria or dysphoria; an increase in the intensity of sensory perception; distortions of time, place, and body image; visual hallucinations; synesthesias (i.e., seeing sounds and hearing colors); illusions; loss of spatial sense; and feelings of unreality. The visual hallucinations are characteristically nebulous, rapidly changing, and unreal (e.g., streaks and blobs of color or kaleidoscopic, multicolored shifting patterns). Visions and mystical experiences have been described. Hallucinogenic drug effects may be variable, even in the same individual on different occasions. The person is usually awake and may appear hyperalert, but is often quiet, calm, withdrawn, depressed, uncommunicative, and oblivious to surroundings or preoccupied with internal stimuli. For some people, the psychedelic experience may be frightening or terrifying, which results in anxiety, agitation, violence, or panic (e.g., a bad trip or bummer). In general, tryptamine, amphetamine derivatives, and mescaline have clinical effects similar to those of LSD. The most common presentation is acute panic reactions. The patients typically present with anxiety, apprehension, a sense of loss of self-control, and frightening illusions.

The subjective effects of LSD (e.g., alterations of mood, perceptual changes, and cognitive impairment) typically begin within 30 to 60 minutes, peak at 2 to 4 hours, and return to baseline within 12 hours. Although LSD may induce profound perceptual changes, there is a lack of good data to suggest adverse physical events as a direct consequence of LSD administration. There does not appear to be a documented case of LSD overdose death. However, massive LSD overdose has resulted in
severe autonomic effects such as coma, toxic psychosis, hyperventilation, respiratory arrest, hypertension, hyperthermia, tachycardia, athetosis, dystonic movements, and coagulopathy \[25,26\]. LSD use has been associated with Serotonin syndrome. An adverse consequence attributed to LSD use that is recognized in DSM-V is “Hallucinogen Persisting Perception Disorder” or “flashbacks,” a condition in which a person re-experiences, following the cessation of hallucinogen exposure, perceptual symptoms that were experienced while intoxicated with the hallucinogen \[27\]. “Flashbacks” can be triggered by stress, illness, and exercise. Persistent LSD effects may include prolonged psychotic reactions, depression, and exacerbation of pre-existing psychiatric illness.

The initial effects of morning glory seeds are listlessness, apathy, and irritability, followed by mild LSD-type effects. Severe psychedelic reactions as well as “flashbacks” have been reported \[28\].

The effects of “magic mushrooms” may include mydriasis, tachycardia, hypertension, hyperreflexia, facial or truncal flushing, behavior, emotional or mood alterations (e.g., dysphoria and frightening experiences or “bad trips”), perceptual disorders (e.g., visual distortions, hallucinations, distortions of body image or depersonalization, and paraesthesias), and panic attacks \[29\]. The experience of serious negative effects (e.g., bad trip) is probably a reason for seeking medical care. In these cases, the individuals may be severely agitated, confused, extremely anxious, disoriented with impaired concentration and judgment (e.g., walking beside a railway line), and acutely psychotic experiencing bizarre and frightening images, severe paranoia, and total loss of reality with consequent accidents, self-injury or suicide attempts. A “bad trip” is usually followed by faintness, sadness and depression and paranoid interpretations, which may persist for months. Some of these symptoms may be associated with concomitant use of other illicit substances. For some individuals, the use of “magic mushrooms” may exacerbate underlying personality disorders and psychosis-like states. Flashbacks have been reported following psilocybin intoxication \[30\]. Intravenous injection of \textit{Psilocybe} mushroom extract has resulted in systemic autonomic effects that include nausea, protracted vomiting, diarrhea, rigors, hyperpyrexia, arthralgias, severe myalgias, loin pain, headache, and skin eruptions. Laboratory results included hypoxemia, leukocytosis with a left shift, elevated renal and liver function studies, and mild methemoglobinemia.

The purported hallucinogenic effects that may be derived from licking the skin of live toads of the genus \textit{Bufo} may be clinically inconsequential compared with the serious effects of the cardioactive compounds (e.g., cardiac dysrhythmias and death); see Chapter 100.

DMT effects include colorful visual hallucinations (e.g., rapidly moving, multidimensional, kaleidoscopic display of intensely colored abstract and
representational images), auditory effects that were not frank hallucinations, dissociation of awareness from the physical body, transient anxiety, a dream-like state, euphoria, and feelings of alternating heat and cold, which usually peaks after a few minutes and resolve within 30 minutes [31].

Peyote can have strong emetic effects, and has been reported to cause profound nausea and vomiting preceding hallucinations.

**Diagnostic Evaluation**

Hallucinogen intoxication is a clinical diagnosis. It is based on a history of possible hallucinogen exposure associated with clinical findings consistent with hallucinogenic effects. The history should include a prior drug abuse and psychiatric illness. Often, the name of the drug is not given but the route of intoxication and dosage form are described (e.g., ate a paper, chewed a button, put acid in my eye). Sometimes the only history is “on a trip.”

Physical examination should focus on eliciting signs of autonomic disturbances, synesthesias, illusions, hallucinations, delusions, and abnormal behavior. Laboratory tests should include serum electrolytes, blood urea nitrogen, creatinine, glucose, CPK, and urinalysis. Urine toxicology screen may confirm the diagnosis of psychedelic hallucinogen intoxication and may be useful in patients with unexplained hallucinations. Quantitative hallucinogen drug levels are not clinically useful and do not contribute to patient management. Although laboratory tests are available for LSD and its metabolite, it is not part of most standard drug abuse screens. Electrocardiogram, arterial blood gas, imaging studies, and lumbar puncture should be obtained as clinically indicated.

**Management**

Management of hallucinogenic tryptamine is similar to that for PCP exposure. The patients should be placed in a quiet area with limited stimuli accompanied by a patient advocate. The advocate should provide reality testing and reassure the patient that it is a drug-induced experience and the adverse drug event will resolve within a few hours. This approach may not be practical or effective for severely disturbed or uncommunicative patients, and liberal intravenous benzodiazepine doses should be administered to control anxiety. Depressed or withdrawn patients are unpredictable and should be kept under close observation.
GI decontamination is unlikely to benefit a symptomatic patient and is not indicated. In patients exhibiting serotonin syndrome, treatment with chlorpromazine or cyproheptadine may be considered (see Chapter 125). The patients are expected to completely recover within 24 hours. Persistent signs and symptoms may be caused by a psychiatric condition precipitated by the hallucinogenic drug, and the patient should be referred to the psychiatric service for evaluation.
REFERENCES

Nonsteroidal anti-inflammatory drugs (NSAIDs) include aspirin, related salicylates (Table 122.1), and a variety of other drugs (e.g., ibuprofen, indomethacin, phenylbutazone, and ketorolac), which modulate inflammation by inhibiting cyclooxygenase (COX). In clinical use for 100 years, aspirin still enjoys widespread popularity in the adult population, both by self-medication and by physician-recommended usage.

While the institution of child-resistant packaging and concerns about Reye’s syndrome resulted in a dramatic decline in pediatric overdose, aspirin remains a leading cause of death due to pharmaceutical overdose [1–3]. Reducing the amount of aspirin available over the counter was associated with fewer overdose deaths in the United Kingdom [4]. Nevertheless, vigilance remains necessary because chronic salicylate intoxication, particularly in the elderly, is commonly unrecognized or mistaken for other conditions, such as sepsis, dehydration, dementia, and multiorgan failure. In contrast, most other NSAIDs have a substantially greater safety margin than aspirin in overdose. Although availability without prescription has resulted in increased use and frequency of overdose, significant acute toxicity is uncommon [1,5,6].

**PHARMACOLOGY**

All NSAIDs have analgesic and antipyretic as well as anti-inflammatory activities. These effects are due to inhibition of COX, also known as prostaglandin G/H synthase, the enzyme responsible for the conversion of arachidonic acid to prostaglandins and thromboxanes [7]. The analgesic dose of most NSAIDs is approximately one-half the anti-inflammatory dose. For some NSAIDs, such as aspirin, ibuprofen, and fenoprofen, this gap is larger, whereas the converse is true for sulindac and piroxicam. Antipyretic effects appear to be due to decreased pyrogen production peripherally as well as to a central hypothalamic effect. The existence of central nervous system (CNS) sites of action mediating analgesic activity has been postulated [8].

Two isoforms of COX have been characterized: COX-1, constitutionally present in platelets, endothelium, gastric mucosa, and the kidneys; and COX-2, induced by a variety of inflammatory mediators (e.g., cytokines, endotoxin, growth factors, hormones, and tumor promoters) but suppressed by glucocorticoids [7]. The anti-inflammatory and analgesic properties of NSAIDs appear to be primarily due to the inhibition of COX-2. Their adverse effects on gastric mucosa (e.g., hemorrhage, ulceration, and perforation) and kidney function (e.g., decreased renal blood flow and glomerular filtration rate), and their effects on platelet function appear to be mediated primarily by COX-1 [7,9,10].
NSAIDs can be classified on the basis of their selectivity for COX-2. In particular, the coxibs rofecoxib, valdecoxib, and celecoxib were developed specifically for their COX-2 selectivity and the promise of improved safety. However, an increased risk of myocardial infarction and stroke was identified in clinical trials and led to regulatory restrictions [11,12]. These adverse cardiovascular effects appear to be due to a relative excess of COX-1–generated thromboxane A$_2$, which is vasoconstrictive and platelet-activating (i.e., prothrombic), and a relative lack of COX-2–generated prostaglandin I$_2$ (prostacyclin), which is vasodilatory and platelet inhibitory (i.e., antithrombotic) [7,11]. It is important to note that traditional NSAIDS diclofenac, meloxicam, and nabumetone exhibit partial COX-2 selectivity, and that other traditional, nonselective NSAIDs may also contribute to adverse cardiovascular events. Thus, selectivity is relative, and all NSAIDs inhibit both COX isoforms in a dose-dependent manner. Inhibition of COX-1 may result in increased lipoxygenation of arachidonic acid to leukotrienes. This alternate metabolic pathway seems to be responsible for the sometimes fatal allergic reactions to NSAIDs especially prevalent in adults with asthma and nasal polyps [13,14].

Aspirin (acetylsalicylic acid) is unique in that it acetylates a serine residue near the active site of COX, thereby irreversibly inhibiting its catalytic function. In contrast, the inhibition of COX by other NSAIDs is reversible and transient. This difference in activity is most notable in platelets, in which thromboxane A$_2$ is essential for normal function [15]. Even in low doses (80 mg), aspirin inhibits platelet aggregation and prolongs the bleeding time for up to 1 week (pending the production of new platelets), whereas other NSAIDs do not have clinically significant effects on platelets [16].

In high doses, aspirin and other salicylates also inhibit the hepatic synthesis of clotting factor VII and, to some degree, factors IX and X, thereby prolonging the prothrombin time. This effect appears to be due to interference with the activity of vitamin K and can be reversed by administration of phytonadione (vitamin K$_1$). In contrast, other NSAIDs have insignificant effects on clotting-factor synthesis [16].

**Salicylates**

Salicylates are available in oral, rectal, and topical formulations. Entericoated and sustained-release aspirin tablets are also marketed. Aspirin preparations frequently contain other drugs such as anticholinergics, antihistamines, barbiturates, caffeine, decongestants, muscle relaxants, and opioids. The recommended pediatric dose of aspirin is 10 to 20 mg per kg of body weight every 6 hours, up to 60 mg/kg/d; for adults, the recommended dose is 1,000 mg initially, followed by 650 mg every 4
hours for anti-inflammatory effect. Multiple formulations of other salicylate salts exist with various indications, and may contain very high concentrations of salicylate (see Table 122.1). After a single oral dose of aspirin, therapeutic effects begin within 30 minutes, peak in 1 to 2 hours, and last approximately 4 hours.

Being a weak acid ($pK_a$, 3.5), aspirin is predominantly nonionized at gastric pH and, therefore, theoretically well absorbed in the stomach. However, gastric acidity slows the dissolution of tablets. Hence, most absorption actually occurs in the small intestine, probably because of its much larger surface area and despite its higher pH. Peak serum salicylate levels of 10 to 20 mg per dL (0.7 to 1.4 mmol per L) occur 1 to 2 hours after ingestion of a single therapeutic dose. Levels up to 30 mg per dL can occur with long-term therapy and may be targeted for maximal anti-inflammatory effects in some patients. Absorption is delayed or prolonged after ingestion of enteric-coated or sustained-release preparations and suppository use [17]. With overdose, slow pill dissolution, and delayed gastric emptying due to aspirin-induced pylorospasm may lead to absorption continuing for 24 hours or longer after ingestion [18,19].

During absorption, aspirin is rapidly hydrolyzed to its active metabolite, salicylic acid. At physiologic pH, salicylic acid ($pK_a$, 3.0) is more than 99.9% ionized to salicylate, which, in contrast to nonionized salicylic acid, diffuses poorly across cell membranes. The drug may become sequestered preferentially in inflamed tissue due to this pH-dependent ionization.

The apparent volume of distribution of salicylate at pH 7.4 is only 0.15 L per kg at therapeutic doses, in part due to its extensive protein binding. Only free (i.e., unbound) salicylate is pharmacologically active. However, salicylate is somewhat unique in that its apparent volume of distribution is not constant. Higher drug levels as a result of chronic therapeutic dosing or acute overdose, low albumin levels, and the presence of other drugs that bind to albumin increase the amount and fraction of free drug. When this occurs, the apparent volume of distribution may increase to 0.60 L per kg [20]. Acidemia, as a consequence of either concomitant illness or severe poisoning, may further increase the fraction of nonionized, diffusible drug, promote its tissue penetration, and increase the apparent volume of distribution even more.

After single therapeutic doses, salicylate is metabolized in the liver to the inactive metabolites salicyluric acid (the glycine conjugate; 75% of the
dose), salicylphenolic glucuronide (10%), salicylacyl glucuronide (5%),
and gentisic acid (less than 1%). The remaining 10% of the dose is
excreted unchanged in the urine. When serum concentrations exceed 20
mg per dL, the two main pathways of metabolism become saturated, and
elimination changes from first order (i.e., proportional to the serum level)
to zero order (constant), as described by Michaelis–Menton kinetics.
Hence, the apparent half-life of salicylate is 2 to 3 hours after a single
therapeutic dose, 6 to 12 hours with chronic therapeutic dosing (i.e.,
serum levels of 20 to 30 mg per dL), and 20 to 40 hours with overdose
(i.e., when levels exceed 30 mg per dL) [21]. Because of saturable
metabolism, a small increase in the daily dose can lead to a large increase
in serum drug levels, with the potential for unintentional poisoning [22].
Depletion of glycine stores may reduce the capacity of the salicyluric acid
pathway and further slow elimination in overdose [23].
Renal excretion of salicylate becomes the most important route of
elimination when hepatic transformation becomes saturated. The rate of
excretion is determined by the glomerular filtration, active proximal
tubular secretion of salicylate, and passive distal tubular reabsorption of
salicylic acid. Alkalization of the urine decreases the passive
reabsorption of salicylic acid by converting it to ionized, nondiffusible
salicylate and thereby increases drug excretion. Similarly, increasing the
rate of urine flow increases drug clearance by increasing the glomerular
filtration and decreasing the distal tubular reabsorption of salicylic acid
(by diluting its concentration in the tubular lumen). Combined
alkalinization and diuresis can augment the renal elimination of salicylate
by 20-fold or more [24,25]. Conversely, dehydration and aciduria
perhaps due to preexisting illness or to salicylate poisoning itself decrease
salicylate excretion, and increase the duration of toxicity once it develops.
Salicylates readily cross the placenta and enter breast milk. Salicylate
elimination in the fetus or infant may be prolonged because of immature
metabolic pathways and renal function [26]. It may also be prolonged in
patients with liver or renal disease.
The pathophysiology of salicylate poisoning is multifactorial [27–30].
Initially and in mild poisoning, direct stimulation of the respiratory
center in the medulla by toxic salicylate concentrations results in a
respiratory alkalosis, unless blunted by concomitant ingestion of CNS
depressants [28]. Direct stimulation of the medullary chemoreceptor
zone and irritant effects on the gastrointestinal tract are responsible for
nausea and vomiting. Exaggerated antipyretic effects involving the
hypothalamus may cause vasodilation and sweating [31]. Dehydration
results from gastrointestinal, skin, and insensible fluid losses. The
osmotic diuresis that occurs as bicarbonate is excreted in response to
alkalemia also contributes to dehydration. Sodium and potassium
depletion result from excretion of these electrolytes along with
bicarbonate (in exchange for hydrogen ion reabsorption). A functional hypocalcemia (decreased ionized calcium) may accompany alkalemia and cause or contribute to cardiac arrhythmias, tetany, and seizures.

Subsequently, in moderate poisoning, the accumulation of salicylate in cells causes uncoupling of mitochondrial oxidative phosphorylation, inhibition of the Krebs cycle and amino acid metabolism, and stimulation of gluconeogenesis, glycolysis, and lipid metabolism [32]. These derangements result in increased but ineffective metabolism, with increased glucose, lipid, and oxygen consumption and increased amino acid, carbon dioxide, glucose, ketoacid, lactic acid, and pyruvic acid production. High serum levels of organic acids contribute to an increased anion-gap metabolic acidosis, and the renal excretion of these acids results in aciduria. However, increased carbon dioxide production further stimulates the respiratory center, and the respiratory alkalosis persists, resulting in alkalemia with paradoxical aciduria.

In severe poisoning, progressive dehydration and impaired cellular metabolism cause multisystem organ dysfunction. Metabolic acidosis with acidemia becomes the dominant acid–base disturbance. Respiratory acidosis, lactic acidosis, and impaired renal excretion of organic acids due to dehydration and acute tubular necrosis contribute to the acidemia. Acidemia increases the fraction of nonionized salicylate in serum, thereby promoting its tissue penetration and toxicity, and precipitous clinical deterioration may ensue with increasing brain salicylate levels. Impaired cellular metabolism can cause increased capillary permeability leading to cerebral edema and noncardiogenic pulmonary edema or acute respiratory distress syndrome. Coma, hyperthermia, and seizures may result from impaired cellular metabolism, cardiovascular depression, cerebral edema, acidemia, hypoglycemia, and acute white matter damage due to myelin disintegration and activation of glial caspase-3 [33,34]. Respiratory alkalosis may be replaced by respiratory acidosis if coma or seizures cause respiratory depression. Tissue hypoxia resulting from pulmonary edema, impaired perfusion, or seizures may lead to anaerobic metabolism and concomitant lactic acidosis.

Hemorrhagic diathesis may result from increased capillary fragility, decreased platelet adhesiveness, thrombocytopenia, and coagulopathy secondary to liver dysfunction. It occurs primarily in patients with chronic poisoning.

Other Nonsteroidal Anti-Inflammatory Drugs
Despite their structural diversity, the pharmacokinetics of traditional NSAIDs are quite similar. Like aspirin, they are weak acids, with $pK_a$ ranging from 3.5 to 5.6 and pH-dependent ionization being the major determinant of tissue distribution and sequestration. They are rapidly absorbed after ingestion, have small volumes of distribution (0.08 to 0.20 L per kg), and are 90% to 99% protein bound (principally to albumin). Most have half-lives of less than 8 hours, with low non–flow-dependent hepatic clearance, primarily by the CYP2C subfamily of cytochrome P450 enzymes, to inactive metabolites that are then conjugated, mostly with glucuronic acid, and excreted in the urine. Sulindac is one exception in that its sulfide metabolite is the active form of the drug and has a half-life of 16 hours [35]. Nabumetone is also a prodrug, and its active metabolite, 6-methoxy-2-naphthylacetic acid, has a half-life of more than 20 hours (and even longer in the elderly) [36]. Phenylbutazone, oxyphenbutazone, and piroxicam are notable for half-lives of longer than 30 hours. Diflunisal, like aspirin, has a dose-dependent half-life of 5 to 20 hours. Indomethacin, sulindac, etodolac, piroxicam, carprofen, and meloxicam undergo enterohepatic recirculation [35,37,38]. Small amounts (less than 10%) of nonsalicylate NSAIDs are excreted unchanged in the urine, limiting the effect of urine pH on clearance. The coxibs are nonacidic drugs [10], highly protein bound and primarily metabolized in the liver.

In contrast to salicylates, the metabolism of most nonsalicylate NSAIDs is not saturable or prolonged in overdose, and elimination follows first-order kinetics. An exception is phenylbutazone, whose elimination may follow Michaelis–Menton kinetics.

Toxic effects of NSAIDs appear to be primarily due to exaggerated pharmacologic effects, with gastric irritation and renal dysfunction resulting from the inhibition of prostaglandin synthesis. In contrast to salicylate poisoning, the acidosis that sometimes occurs with large overdoses of these agents appears to be due to high levels of parent drug and metabolites rather than to disruption of metabolism [39].
Salicylate poisoning may occur with acute as well as chronic overdose [27–30,40–46]. It most commonly results from ingestion, but poisoning due to topical use [47] and rectal self-administration [48] has been reported. The ingestion of topical preparations of methyl salicylate (oil of wintergreen, also present in Chinese propriety medicines) can result in rapid-onset poisoning, due to its concentration, rapid absorption kinetics, and higher lipid solubility. Infants may become poisoned by ingesting the breast milk of women chronically taking therapeutic doses of salicylate [49]. Intrauterine fetal demise resulting from poisoning during pregnancy [50] and neonatal poisoning resulting from the transplacental diffusion of therapeutic doses of salicylate taken before delivery [51] have also been described. Delays to presentation, diagnosis, and chronicity increase the severity and mortality [42,52,53]. With severe poisoning, the fatality rate may be as high as 50% [43,46].

Regardless of whether poisoning is acute or chronic, it can be characterized as mild, moderate, or severe on the basis of the serum pH and underlying acid–base disturbance (Table 122.2). This approach was first described in the classic papers by Done [40,54], who also developed a nomogram that attempted to correlate the severity of poisoning with a timed salicylate level after acute ingestion. Although Done’s nomogram has subsequently been shown to have poor predictive value [41,52], his observation that the clinical severity of poisoning correlates with acid–base status remains undisputed.

### TABLE 122.2 Severity of Salicylate Poisoning

</tr>
</tbody>
</table>
Mild poisoning is characterized by alkalemia (serum pH greater than 7.45) and a pure respiratory alkalosis. It may develop 2 to 8 hours after acute ingestion of 150 to 300 mg per kg of aspirin [40,54] or any time during chronic therapy. Associated signs and symptoms include nausea, vomiting, abdominal pain, headache, tinnitus, tachypnea (or subtle hyperpnea), ataxia, dizziness, agitation, and lethargy. The anion gap (see Chapter 198) is normal until late in this stage, when compensatory renal bicarbonate excretion eventually lowers the serum bicarbonate level. Serum glucose, potassium, and sodium values may be high, low, or normal. Despite total body fluid and electrolyte depletion and clinical dehydration, laboratory evidence of dehydration (e.g., hemoconcentration, increased serum blood urea nitrogen [BUN] and creatinine, increased urine specific gravity) may be absent.

Moderate poisoning is characterized by a near normal serum pH (7.35 to 7.45) with an underlying metabolic acidosis as well as respiratory alkalosis. It can occur 4 to 12 hours after an acute overdose of 300 to 500 mg per kg of aspirin [40,54]. It may also occur in patients with chronic ingestion who delay seeking medical care for symptoms of mild poisoning and continue to take salicylate. Electrolyte analysis demonstrates a low serum bicarbonate value with an increased anion gap. Gastrointestinal and neurologic symptoms are more pronounced. There may be agitation, asterixis, diaphoresis, deafness, pallor, confusion, slurred speech, disorientation, hallucinations, tachycardia, tachypnea, and orthostatic hypotension. Leukocytosis, thrombocytopenia, increased or decreased serum glucose and sodium values, hypokalemia, and increased serum BUN, creatinine, and ketones may be present.

Severe poisoning is defined by the presence of acidemia (serum pH less than 7.35) with underlying metabolic acidosis and a high anion gap. It can occur 6 to 24 hours or more after the acute ingestion of more than 500 mg per kg of aspirin [40,54] or in unrecognized or untreated chronic poisoning. Severe dehydration and marked sinus tachycardia are often present. Other findings may include coma, seizures, papilledema,
hypotension, dysrhythmias, congestive heart failure, oliguria, hypothermia or hyperthermia, rhabdomyolysis, and multiple organ failure [46,53,55]. Hypoglycemia, pulmonary edema, and cerebral edema or hemorrhage may be present [45]. Asystole is the most common terminal dysrhythmia, but ventricular tachycardia and ventricular fibrillation can also occur [45,46,56,57]. When cardiac arrest occurs, death appears to be inevitable. Successful resuscitation in this situation has yet to be reported [57].

Although an increased anion-gap metabolic acidosis is often said to be a hallmark of salicylate poisoning, in reality a variety of acid–base disturbances may be seen depending on the delay to presentation and severity of poisoning. As noted earlier, the anion gap may be normal and acidosis absent in early or mild intoxication. In addition, the anion gap is rarely above 20 mEq per L, even in advanced poisoning [28]. In adults, combined respiratory alkalosis and metabolic acidosis is the most common finding (50% to 61%), followed by pure respiratory alkalosis (20% to 25%), pure metabolic acidosis (15% to 20%), and a combined respiratory and metabolic acidosis (5%) [28,46]. Metabolic acidosis is more common and respiratory alkalosis more often absent in children than in adults [42,46] suggesting that children progress more rapidly from mild to severe poisoning, perhaps because of more rapid and extensive tissue distribution of drug [58]. Metabolic acidosis is also more common in patients with large acute ingestions, chronic intoxication, and delayed presentation or treatment [28,42,43,46,59]. The onset and progression of toxicity may be delayed after overdose with enteric-coated or sustained-release formulations [17].

Potential complications of both therapeutic and toxic doses of salicylate include gastrointestinal tract bleeding, increased prothrombin time, hepatic toxicity, pancreatitis, proteinuria, and abnormal urinary sediment. Significant bleeding, gastrointestinal tract perforation, blindness, and inappropriate secretion of antidiuretic hormone are rare complications of acute poisoning.

Other Nonsteroidal Anti-Inflammatory Drugs

With the exception of mefenamic acid and phenylbutazone, significant toxicity from acute overdose is unusual and occurs following massive ingestion. Manifestations typically include nausea, vomiting, abdominal pain, headache, confusion, tinnitus, drowsiness, and hyperventilation [5,60,61]. Glycosuria, hematuria, and proteinuria are also common. Occasionally, acute renal failure (acute tubular necrosis or interstitial nephritis) can develop. Symptoms rarely last more than several hours, and acute renal toxicity is almost always reversible over a period of a few days to weeks. Experience with selective COX-2 inhibitor overdose is
limited, but acute toxicity appears to be similar to nonselective NSAIDS [62].

Muscle twitching and grand mal seizures have been reported in 30% of mefenamic acid overdoses [63]. Apnea, coma, and cardiac arrest can also occur [63]. Metabolic acidosis, coma, seizures, hepatic dysfunction, hypotension, and cardiovascular collapse are relatively frequent after phenylbutazone overdose [60,61,64–66]. Uncommonly, coma, hyperactivity, hypothermia, seizures, metabolic acidosis, acute renal insufficiency, thrombocytopenia, acute respiratory distress syndrome, upper gastrointestinal tract bleeding, and respiratory depression are seen in ibuprofen poisoning [39,66–69]. Death from ibuprofen alone is extremely rare [1,5,6]. Seizures and metabolic acidosis have also been reported in ketoprofen and naproxen poisoning [70,71].

Minimum toxic and lethal doses are not well defined. Little correlation was found between the amount of ibuprofen reportedly ingested and symptoms in adults [65]. In the pediatric population, however, the mean amount ingested was much greater in symptomatic patients (440 mg per kg) than asymptomatic ones (114 mg per kg) [67]. Elderly patients are at increased risk of developing toxicity with both therapeutic doses and overdoses. Even with severe poisoning, complete recovery usually occurs within 24 to 48 hours.
DIAGNOSTIC EVALUATION

The history should include the time or times of ingestion, the specific product and formulation, the amount ingested, and any concomitant ingestion or medication use. Physical examination should focus on vital signs, neurologic and cardiopulmonary function, and assessment of the state of hydration. Vital signs should include an accurate temperature and respiratory rate and, if possible, orthostatic measurements of pulse and blood pressure. The abdomen should be evaluated for peritoneal signs suggestive of perforation. The urine should be tested for pH, ketones, and occult blood.

Salicylates

Laboratory evaluation of patients with salicylate poisoning should include arterial or venous blood gases, complete blood cell count, serum electrolyte, glucose, BUN, creatinine, and salicylate levels, and urinalysis. Patients with moderate-to-severe salicylate poisoning should also have serum calcium, magnesium, and ketones, liver function tests, coagulation profile, electrocardiogram, and chest radiograph. Because patients often confuse aspirin and acetaminophen, testing should be performed for both.

The ferric chloride spot test can be used to rapidly detect the presence of salicylate in urine or commercial products [72]. Several drops of 10% ferric chloride turn urine purple if salicylate is present. A positive urine test indicates exposure but not overdose, because positive results are seen with therapeutic dosing. False-positive reactions may be caused by acetoacetic acid, phenylpyruvic acid, phenothiazines, and phenylbutazone. Diflunisal may result in falsely elevated serum salicylate levels when measured by fluorescence polarization immunoassay or the Trinder colorimetric assay [73].

Serum salicylate concentrations must be interpreted with respect to the duration (i.e., acute vs. chronic overdose), time of ingestion, and the serum pH. At similar salicylate concentrations, patients with chronic poisoning tend to be more ill than those with acute poisoning [29,45,46]. Soon after an acute overdose, concentrations can be quite high (e.g., greater than 60 mg per dL) in the absence of significant toxicity. Conversely, with chronic overdosage and late in the course of an acute overdose, moderate or severe toxicity may be present despite serum salicylate concentrations in or just above the high therapeutic range. At similar salicylate concentrations, children, the elderly, and those with underlying disease tend to be more ill than otherwise healthy adults.
Poisoning in such patients, particularly if chronic, can occasionally be seen with therapeutic salicylate levels. Acidemia facilitates passage of drug into the brain, worsening toxicity. Hence, as noted previously, the severity of poisoning is ultimately determined by acid–base status and clinical findings.

Serial salicylate levels are necessary for confirming the diagnosis and monitoring the efficacy of treatment, but do not obviate the need for continued clinical and metabolic monitoring. Depending on the severity and course of poisoning, drug levels and other laboratory tests should initially be repeated at 2-hour intervals. Because of delayed and erratic absorption, it is imperative to demonstrate a falling and near-zero salicylate concentration to exclude significant ongoing absorption after overdose, which generally requires at least 12 hours even in mild overdoses [19].

Historically, approximately 1 in 4 patients with chronic salicylate poisoning are initially undiagnosed [28,43,59]. These patients are typically elderly, have a variety of presenting complaints and underlying illnesses, and have been taking aspirin with therapeutic intent. To avoid missing the diagnosis, all patients should be asked specifically about the use of nonprescription drugs. Asking about tinnitus or hearing distortion, which occurs with salicylate levels in the high end of the therapeutic range (i.e., 20 to 30 mg per dL), may also suggest the diagnosis in patients with unknown ingestions or unexplained complaints. Occult salicylate poisoning should be considered in any patient with an unexplained acid–base disturbance, altered mental status, hyperthermia, diaphoresis, dyspnea, vomiting, or pulmonary edema [28,59].

The differential diagnosis of salicylate poisoning includes infection, CNS trauma and tumors, congestive heart failure, chronic obstructive pulmonary disease, poisoning with carbon monoxide, isoniazid, lithium, and valproate, and other causes of an elevated anion-gap acidosis, particularly methanol and ethylene glycol (see Chapter 198). Hemodynamic, autonomic, and laboratory manifestations of severe poisoning resemble the systemic inflammatory response syndrome and may be mistaken for sepsis [51,55,75]. Salicylate poisoning has also been misdiagnosed as alcohol intoxication, alcohol withdrawal, dementia, diabetic ketoacidosis, impending myocardial infarction, hepatic encephalopathy, and viral encephalitis.

In infants and children, salicylate poisoning may be confused with inborn errors of metabolism. It may be particularly difficult to distinguish from Reye’s syndrome, because they are not only similar in presentation
but appear to be interrelated [76,77]. Fatty infiltration of the liver on pathologic examination of a biopsy specimen, low (i.e., subtherapeutic) cerebrospinal fluid salicylate levels, and high alanine, glutamine, and lysine levels indicate Reye’s syndrome rather than salicylate poisoning. Radiopaque densities in the stomach on abdominal radiograph suggest the possibility of an enteric-coated or sustained-release formulation or a magnesium or bismuth salt of salicylate.

**Other Nonsteroidal Anti-Inflammatory Drugs**

The initial evaluation of patients with nonsalicylate-NSAID overdose is similar to that for salicylates. Evaluation of acid–base, electrolyte, and renal parameters is particularly important. Additional ancillary testing is dictated by clinical severity. Quantitative serum levels of nonsalicylate NSAIDs are neither routinely available nor necessary for treatment. Many medical conditions and other intoxications cause signs and symptoms similar to those seen in nonsalicylate NSAID poisoning. In the absence of a history of ingestion, the diagnosis is made by exclusion of other etiologies.
MANAGEMENT

Salicylates

Supportive care, limiting drug absorption, and enhancing drug elimination are the goals of therapy. Resuscitative measures should be instituted when necessary. It is critically important to remember that, should endotracheal intubation be necessary, hyperventilation must be accomplished before, during, and after this procedure to prevent worsening acidemia, which increases the fraction of nonionized salicylic acid available for tissue distribution, thereby enhancing toxicity. The administration of respiratory depressants or failure to adequately hyperventilate unconscious or paralyzed patients can result in rapid deterioration and death of severely poisoned patients [52, 56, 78]. Because an increase in the partial pressure of carbon dioxide (PCO$_2$) is almost inevitable following intubation and mechanical ventilation, it is recommended that patients with arterial PCO$_2$ values below 20 mm Hg be given an intravenous bolus of 1 to 2 mEq per kg sodium bicarbonate at the time of intubation. Arterial blood gases should always be checked after intubation and after bicarbonate therapy.

Because CNS hypoglycemia may occur despite a normal serum glucose value [79], 50 mL of 50% dextrose in water should be given intravenously to any patient with an altered mental status whose capillary glucose concentration is not elevated [41]. Anticonvulsants (e.g., benzodiazepines, propofol, or barbiturates) as well as supplemental glucose should be given to patients with seizures. It is also prudent to administer sodium bicarbonate to patients who have seizures, as acidemia is likely to worsen. Hyperthermia should be treated with cooling blankets, ice packs, and evaporative methods (see Chapter 185).

Central venous pressure monitoring may be necessary for optimal treatment of hypotension, especially if there is evidence of heart failure or pulmonary edema. Patients with noncardiac pulmonary edema should be treated with positive pressure ventilation rather than diuretics. Again, maintaining hyperventilation and reducing acidemia are critical in patients with compromised pulmonary function.

Additional supportive measures are directed at correction of dehydration and metabolic derangements. The degree of dehydration parallels the severity of poisoning [54], but it is often unappreciated, underestimated, or undertreated. Patients with mild, moderate, or severe poisoning typically have volume deficits of 1 to 2, 3 to 4, or 5 to 6 L (20, 40, and 60 mL per kg in children), respectively. In the presence of acidemia, hypokalemia is more severe than indicated by the serum
potassium level (by approximately 0.6 mEq per L for each 0.1 unit of decrease in pH) and should be treated accordingly. Acidemia should also be treated aggressively with intravenous NaHCO₃. Since the respiratory alkalosis is a concomitant primary acid-base disturbance and not just a compensatory response, the administration of bicarbonate is unlikely to blunt the respiratory drive and increase the PCO₂, which might otherwise limit the change in serum pH. In addition, the goal of therapy is to limit the tissue distribution of salicylates by increasing the serum pH. The dose of bicarbonate needed may be substantial, and is typically 200 to 300 mEq in an adult with severe poisoning.

As with repleting volume, at least half of the NaHCO₃ deficit should be given during the first hour either by continuous infusion or by 0.5 to 1.0 mEq per kg boluses every 10 minutes. Arterial blood gases should be reevaluated during and after such therapy. Potential complications of NaHCO₃ administration include excessive alkalemia, hypokalemia, hypocalcemia, hypernatremia, and fluid overload. Relative contraindications to hypertonic NaHCO₃ include oliguric renal failure, congestive heart failure, and cerebral or pulmonary edema. Tetany should be treated with intravenous calcium chloride or calcium gluconate (10 mL of a 10% solution over 5 to 10 minutes). Fresh-frozen plasma, red blood cell, and platelet transfusions may be required for patients with active bleeding or significant blood loss. Asymptomatic increases in international normalized ratio can be treated with subcutaneous vitamin K.

Gastrointestinal decontamination should be performed in all patients with intentional overdoses and those with accidental ingestions of greater than 150 mg per kg. Because of delayed absorption, decontamination may be effective for as long as 24 hours after overdose, even in patients with spontaneous vomiting [18]. Considerable diversity of opinion exists, however, regarding the optimal method of decontamination [80].

Activated charcoal is effective in preventing salicylate absorption and, therefore, it is recommended for all significant ingestions, regardless of delay in presentation. Multiple oral doses of charcoal [81] or gastric lavage preceded and followed by activated charcoal may be even more effective for preventing the absorption of large overdoses [82]. Many grams of aspirin have been recovered by lavage up to 24 hours after ingestion [18]. Repeated doses of activated charcoal or whole-bowel irrigation may be effective for patients who have ingested enteric-coated
or sustained-release formulations and those with serum drug levels that continue to rise despite other decontamination measures [83].

The efficacy of multiple-dose charcoal therapy in enhancing salicylate elimination may depend on the formulation. Increases in serum salicylate elimination reported using an effervescent preparation containing bicarbonate [84] could not be replicated with multiple doses of non-effervescent charcoal in simulated overdose (i.e., less than 3 g) in humans [85–88]. Oral charcoal did not substantially accelerate the elimination of intravenously administered salicylic acid, discounting the role of gut dialysis or enterohepatic circulation [89]. If multiple-dose charcoal is used, sorbitol should not be included with the subsequent doses [90,91].

Salicylate elimination can be enhanced by urine alkalinization and diuresis [24,25,29,92], extracorporeal removal [93], and perhaps by glycine administration [44]. It should be emphasized that alkalinizing the serum and urine, and establishing a urine output of 1 to 2 mL/kg/h are critically important goals in the management of patients with salicylate toxicity [30,94]. Moreover, alkalinization of the urine is difficult to achieve in patients with acidemia and aciduria (i.e., severe clinical toxicity) [54]. Theoretical concerns regarding pulmonary or cerebral edema should not preclude aggressive fluid therapy, as administering only maintenance fluids intravenously is insufficient treatment for a patient with salicylate poisoning.

Indications for urine alkalinization and alkaline diuresis include acid-base abnormalities and systemic symptoms with a salicylate level that is greater than 30 mg per dL after an acute overdose. Patients with chronic overdoses may be symptomatic and require treatment at lower salicylate levels. The goal is to achieve a urine pH of 7.5 or greater. All patients treated with alkaline diuresis need close monitoring in an intensive care unit or step down setting. Bladder catheterization is essential in those with moderate or severe poisoning, as hourly monitoring of urine output and pH is required. Arterial or venous blood gases, electrolytes, BUN, creatinine, glucose, and salicylate concentrations should initially be rechecked at 2-hour intervals, depending on the severity of poisoning, the results of previous testing, and the response to therapy. Cardiac monitoring and frequent reevaluations of vital signs, mental status, and pulmonary function are also necessary during alkaline diuresis [94].

Alkalinization of the urine may be impossible to achieve in the presence of either dehydration or hypokalemia, because hydrogen ions are excreted in exchange for reabsorbed sodium and potassium, respectively [52]. Therefore, correction of fluid and potassium deficits is critical.

The amount of bicarbonate and supplementary potassium necessary to achieve and maintain an alkaline urine depends on the severity of
poisoning (Table 122.2). For example, after 1 to 2 L of crystalloid by bolus, the initial intravenous fluids for a moderately poisoned adult could be 1 L over 2 hours of 5% dextrose in one-half normal saline to which 75 mEq of sodium bicarbonate (i.e., 1.5 ampules of 8.4% sodium bicarbonate) and 40 mEq of potassium chloride have been added. In severe poisoning, however, 150 mEq of sodium bicarbonate (i.e., 3 ampules of 8.4% sodium bicarbonate) and 60 mEq of potassium chloride should be added to each liter of 5% dextrose in water, and adjusted as necessary. In patients with hypernatremia, a more hypotonic solution should be used. Again, the use of a dextrose-containing solution is important because of the potential for occult CNS hypoglycemia. Although forced diuresis (e.g., 500 mL per hour urine output in adults) is no longer recommended [94,95], achieving a moderate diuresis (1 to 2 mL/kg/h) is recommended. While counterintuitive, even patients with mild poisoning (i.e., alkalemia) should be given bicarbonate (and fluids) to replace ongoing renal losses and prevent deterioration.

Carbonic anhydrase inhibitors (e.g., acetazolamide) should never be used to alkalinize the urine, because the resultant systemic acidosis may promote tissue distribution of salicylate and result in clinical deterioration [96,97]. Similarly, the use of tris-hydroxymethyl aminomethane, an organic H+ buffer, to increase serum and urine pH is not recommended. Although tris-hydroxymethyl aminomethane has been suggested for the treatment of acidemia and aciduria refractory to bicarbonate administration, it has not been studied in human salicylate poisoning and has a number of potential adverse effects (e.g., hypoglycemia, extravasation necrosis, phlebitis, respiratory depression, and increased intracellular pH leading to decreased pH gradients with increased tissue distribution and intracellular trapping of salicylate) [98].

The complications of alkaline diuresis include excessive alkalemia, hypokalemia, hypocalcemia, hypernatremia, and fluid overload [44,94,95]. Young children, the elderly, and those with severe poisoning are most susceptible to such complications. Alkaline diuresis is contraindicated in patients with oliguric renal failure, congestive heart failure, and cerebral or pulmonary edema. Such therapy should be withheld or discontinued if the serum pH exceeds 7.55.

Hemodialysis is indicated in patients with severe poisoning and those with moderate poisoning who fail to improve with alkaline diuresis [30,31,43,44,52,93]. Hemodialysis is essential in patients with coma, seizures, cerebral or pulmonary edema, and renal failure [31,46]. Hemodialysis should also be strongly considered when patients demonstrate any impairment in the level of consciousness, rather than waiting for unresponsiveness or coma [93]. Acidemia and temperature greater than 38°C are associated with high mortality [46] and should also be considered potential indications for hemodialysis, particularly if the
patient is resistant to bicarbonate and fluid therapy. Similarly, patients with moderate poisoning who have liver dysfunction and, hence, impaired ability to eliminate salicylate may also benefit from hemodialysis.

A high salicylate level is often cited as a stand-alone indication for hemodialysis but recommendations vary widely, with cutoffs ranging from 40 to 200 mg per dL (100 mg per dL being the most common) for acute ingestions and 60 to 80 mg per dL for chronic exposures [98]. A recent international multidisciplinary group “recommended” extracorporeal treatment when concentrations exceed 100 mg per dL, and “suggested” it for concentrations over 90 mg per dL, based on “very weak” evidence [93]. In one study [43], salicylate levels in fatal cases ranged from 34 to 193 mg per dL and in another [45], some patients died with drug levels in the therapeutic range. Moreover, drug levels do not discriminate patients who die from survivors [45,46]. Clearly, the salicylate level should not be used as the sole indication for hemodialysis. Instead, the severity of poisoning is determined by clinical findings, which reflect tissue drug concentration, and do not necessarily correspond to blood levels, especially when acidemia is present [96]. Moreover, a serum salicylate concentration should be interpreted in the context of a simultaneous measurement of serum pH. Hence, hemodialysis is appropriate for patients with high drug levels who have severe clinical toxicity (particularly acidemia), but it may not be necessary in those without such manifestations [46]. Conversely, patients with low salicylate levels, particularly those with significant underlying cardiorespiratory disease, should be treated with hemodialysis if they exhibit clinical or laboratory manifestations of severe toxicity. Because of delays inherent in the turnaround time for measuring salicylate and in preparing for hemodialysis, the projected clinical course should also be considered. Waiting for the salicylate level to reach some predetermined level before initiating hemodialysis in patients who are severely poisoned or deteriorating despite other treatments is ill-advised.

Hemodialysis is preferred over continuous renal replacement therapy or hemoperfusion due to the rapid clearances and correction of fluid, electrolyte, and acid–base abnormalities achieved [93,99]. Peritoneal dialysis and exchange transfusion are also less effective [100]. A high-bicarbonate (e.g., up to 40 mEq per L) dialysate solution (bath) should be used, and potassium should usually be added to the dialysate solution. Hemodialysis should be performed for at least 4 to 6 hours, and salicylate concentrations are below 20 mg per dL [93].
Failure to adequately correct fluid deficits prior to initiating hemodialysis can result in disastrous consequences. In contrast to the typical dialysis (i.e., renal failure) patient who is fluid overloaded, those with salicylate poisoning are typically hypovolemic. Uncorrected or occult hypovolemia can result in cardiovascular decompensation with hemodynamic instability, and even cardiac arrest, when dialysis is started because of the acute decrease in intravascular volume that can occur at the beginning of dialysis. This complication can be prevented or minimized by ensuring adequate volume resuscitation, and priming the tubing and pump with saline (rather than blood) prior to initiating dialysis.

Oral administration of glycine or N-glycylglycine has been used in overdose patients to promote drug clearance [23,101]. Because the conjugation of salicylic acid with glycine to form salicyluric acid becomes saturated and glycine levels decrease in overdose patients, supplemental glycine can enhance the formation and excretion of this metabolite. To date, clinical experience with this therapy is limited, its comparative efficacy is unknown, and the side effects of nausea and vomiting with glycine have been problematic. Doses used ranged from 8 g dissolved in water initially, followed by 4 g every 4 hours for 16 hours, to 20 g followed by 10 g every 2 hours for 10 hours for glycine. The dose for N-glycylglycine was 8 g dissolved in water followed by 2 to 4 g every 2 hours for 16 hours.

Other Nonsteroidal Anti-Inflammatory Drugs

The treatment of nonsalicylate NSAID poisoning is supportive and symptomatic, and most patients require only observation. However, airway protection and mechanical ventilation, fluid resuscitation, anticonvulsants for seizures, bicarbonate for acidosis, and blood products for gastrointestinal tract bleeding may occasionally be required. Renal function should be monitored carefully in patients with abnormal urinalysis, underlying renal disease, or advanced age. Liver function tests should be followed in patients with severe phenylbutazone and piroxicam poisoning [66].

Gastrointestinal decontamination with activated charcoal should be considered for patients who present soon after a significant ingestion, defined as greater than ten therapeutic doses in adults and more than five adult doses in children [60,61]. Although charcoal hemoperfusion has been used to treat a patient with severe phenylbutazone poisoning who had impaired renal and hepatic function [64], extracorporeal elimination measures are unlikely to be effective because of the high-protein binding and rapid intrinsic elimination of these agents. Multiple-dose charcoal therapy enhances the elimination of therapeutic doses of phenylbutazone
by 30% [102] and may be similarly effective for other agents, but the clinical benefit of such therapy after overdose is likely to be limited.

Sedative-hypnotics include benzodiazepines (BZDs), barbiturates, non-BZD/nonbarbiturate agents (NBNBs). In the 1960s, NBNBs, such as meprobamate, were introduced and became popular. NBNBs have been mostly supplanted by BZDs, which have greater efficacy and a larger therapeutic ratio, and are currently one of the most widely prescribed classes of drug (Table 123.1). BZDs and their derivatives are used to treat anxiety, depression, panic disorders, insomnia, musculoskeletal disorders, seizures, and alcohol withdrawal, and are used as adjuncts for anesthesia and procedural sedation. The chronic use of all sedative-hypnotics can result in physical tolerance, addiction, misuse, and withdrawal syndromes on abrupt cessation of therapy. Withdrawal syndromes are discussed in Chapter 126.

BENZODIAZEPINES

Pharmacology
BZDs exert their therapeutic effect at specific BZD receptor sites in the central nervous system (CNS). The BZD receptor is located within the γ-
aminobutyric acid-A (GABA-A) receptor supra-molecular complex (GRSMC). Binding of GABA or GABA plus a BZD causes an allosteric change in the GRSMC. This results in an increase in the frequency of chloride channel opening, with a resultant increase in chloride flux and hyperpolarization. Activation of GRSMC by a BZD potentiates synaptic GABA-mediated inhibition [1]. These GRSMCs are located throughout the brain and spinal cord. GABA is an inhibitory neurotransmitter, and activation of GABA neurons leads primarily to inhibition of dopamine release, although norepinephrine and acetylcholine are also affected. The effect on serotonin release is minimal.

BZD absorption from the gastrointestinal (GI) tract depends on the properties and pharmaceutical formulation of each drug. Peak serum concentration commonly results within 3 hours post-ingestion; intramuscular absorption varies from agent to agent but can be erratic and delayed. Duration of action is dependent on the lipophilicity of each compound: the more lipophilic, the shorter the duration of action. BZDs are highly protein-bound (85% to 99%). Their volume of distribution depends on lipid solubility and varies from 0.26 to 0.58 L per kg for chlordiazepoxide to 0.95 to 2.00 L per kg for diazepam. BZDs are primarily metabolized in the liver by CYP3A4 and then glucuronidated. Metabolism may be reduced by CYP3A4 inhibitors such as fluoxetine [2]. BZDs can be classified on the basis of elimination half-life (Table 123.2).

Fatality from pure BZD overdose is rare. Toxicity is dose-dependent and may vary between individual agents. Alprazolam overdose, in particular, results in more frequent intensive care unit admission, mechanical ventilation, and flumazenil use than other BZDs [3]. A retrospective review of 1,239 overdoses from one medical examiner’s office revealed only two deaths solely related to diazepam overdose [4]. For chronic abusers, rapid clinical recovery after BZD overdose results from adaptation or tolerance to the depressant effects [5].

Clinical Presentation

Overdose commonly occurs as a part of multidrug and or ethanol ingestion. BZDs alone produce slurred speech, lethargy, ataxia, amnesia, nystagmus, and coma. Loss of deep tendon reflexes and apnea are unusual except with a massive overdose. Complications such as pulmonary aspiration, hypoxic cardiac arrest, and acute lung injury are also possible, but are more likely to occur in mixed sedative ingestions.

Diagnostic Evaluation

Recommended laboratory studies include serum electrolytes, creatinine,
and glucose. Because BZDs may be involved in a multidrug overdose, serum acetaminophen concentration and a 12-lead electrocardiogram should also be obtained. Qualitative urine drug screening using immunoassay techniques has limitations in detecting the presence of certain BZDs. Immunoassay technologies are based upon competitive binding between an antibody and antigen. The antibodies used are usually sensitive and specific for a certain drug, which for BZD immunoassays is commonly oxazepam. However, many BZDs do not form oxazepam or similar metabolites during metabolism and may be missed by screening [6]. As a result, it is important to know what screening immunoassay a laboratory uses for urine drug screening, as this will list which agents can and cannot be detected. Quantitative serum BZD concentration estimation is not useful in the clinical management of overdose.

Management

The most important aspect of BZD overdose management is supportive care. Airway management should precede all interventions, and intubation is indicated if the patient cannot adequately maintain spontaneous ventilation or protect the airway. Vascular access should be established. The patient should be placed on continuous pulse oximetry and cardiac monitoring. Activated charcoal (1 g per kg) administration in simple BZD intoxication is unlikely to be of benefit and may be harmful in patients who are initially awake and subsequently become sedated if the airway is unprotected. The risks of charcoal administration to a sedated patient with isolated BZD ingestion must be weighed against the low risk of morbidity and mortality seen with this poisoning. There is no evidence that repeat-dose charcoal enhances BZD elimination [7].

Flumazenil (Romazicon, Anexate) is a BZD antagonist that binds to the GRSMC competitively inhibiting BZD binding and thereby reversing BZD sedative and anxiolytic effects [8]. The effect on BZD-induced respiratory depression is less predictable and it cannot be relied upon to maintain adequate respiratory effort. Flumazenil does not fully reverse the amnestic effects of BZDs. Patients may appear awake and alert, but subsequent recall (e.g., of instructions) may be poor.

For most patients with pure BZD poisoning, supportive care with attention to airway and ventilatory status is all that is required to manage their overdose. It is uncommon for patients to require administration of flumazenil to treat sedation alone. This agent should never be considered in place of airway intervention in compromised patients. As BZDs are
most commonly part of multidrug ingestions, flumazenil use is rarely indicated. Adverse drug events associated with flumazenil use include anxiety, nausea, agitation, and crying. It should particularly be avoided in patients suspected to be BZD-tolerant [9]. Flumazenil may precipitate an abrupt withdrawal syndrome with potential for seizures in these patients. This may occur after short-term use of BZDs [10]. Flumazenil should also be avoided in patients with suspected multidrug ingestion where reversal of BZD effect may unmask the epileptogenic effects of the other drugs (e.g., cyclic antidepressants, isoniazid, or cocaine). Flumazenil is especially contraindicated in patients with electrocardiographic evidence of sodium channel blockade (e.g., cyclic antidepressant poisoning) with prolonged QRS duration. Flumazenil has been suggested as a diagnostic tool for undifferentiated coma and after iatrogenic toxicity. Despite this, its role and indications remain unclear in the management of the BZD-poisoned patient. Flumazenil use does not reduce hospital length of stay or the need for high-dependency monitoring. The response to flumazenil is titratable. If administering flumazenil, the initial dose should be small (0.05 to 0.1 mg). This can be repeated at 30-second intervals. In general, if there is no response after a total dose of 1 mg, the diagnosis of BZD poisoning is unlikely. The aim of therapy is to give enough to have the patient moderately drowsy and easily aroused and not to have the patient awake, alert, and keen to self-discharge from hospital. Flumazenil has a short half-life (approximately 50 minutes); it may be administered as an infusion in severe BZD poisoning, in a fashion similar to naloxone in severe opioid poisoning. Seizures that result from flumazenil therapy may require large doses of BZDs or barbiturates such as thiopental or phenobarbital.
BARBITURATES

Since the development of BZDs and other newer sedative-hypnotics, the prescription of barbiturates and the incidence of severe poisoning has declined. However, as recently as 2011, barbiturates were still in the top 20 most common classes of drugs associated with fatality in the United States [11]. The recommendation that pentobarbital is a good drug for euthanasia in pro-euthanasia resources may also be leading to an increase in self-poisonings with barbiturates obtained illicitly for this purpose [12].

Pharmacology

Barbiturates depress the activity of all excitable tissues. They enhance GABA post-excitatory inhibition and have a binding site on the GABA-A receptor complex, leading to increased chloride flux by increasing the duration of chloride channel opening.

Barbiturates are available in all forms and are classified according to their duration of action. Ultra-short–acting barbiturates are highly lipid soluble and rapidly partition into the CNS, with subsequent redistribution to all tissues. When parenterally administered, they have rapid onset with less than 1-hour duration of effect; their predominant role is for induction of anesthesia. Short- and intermediate-acting barbiturates are intermediate in lipid solubility and are used as anxiolytics and sedatives. Long-acting barbiturates have relatively low lipid solubility and are mainly used as anticonvulsants. Systemic toxicity tends to be a function of the drug’s elimination half-life (Table 123.3).

NA, not available.

Barbiturates are well absorbed from the GI tract; serum concentration and symptoms are detectable within 30 minutes, and their peak effect occurs by 4 hours. Barbiturates are variably metabolized by the liver. Most of the highly lipid-soluble metabolites are renally excreted after glucuronidation. Barbiturates induce microsomal enzymes and increase the metabolism of medications that are CYP substrates. This includes barbiturates themselves resulting in auto-induction of metabolism, which contributes to tolerance. The longer acting barbiturates rely more on
urinary excretion for elimination (phenobarbital, 25% to 33%; barbital, 95%; primidone, 15% to 42%; phenylethylmalonamide a metabolite of primidone, 95%). Renal elimination can be enhanced by urinary alkalization as they are weak acids. The kinetics of barbiturate elimination are mixed: first order at low concentrations and zero order at high ones [13]. Therapeutic serum drug concentration is between 10 and 40 μg per mL for phenobarbital and 1 to 5 μg per mL for the short-acting barbiturates. Toxic dose is in the range of 6 to 10 g for the long-acting barbiturates and 3 to 6 g for the short-acting ones. Most patients demonstrate some degree of sedation after ingestion of more than 8 mg per kg. Tolerance rapidly develops, and chronic users may require 5 to 10 times the normal dose for sedation. Depending on the degree of tolerance, the drug concentration associated with coma ranges from 80 to 120 μg per mL for phenobarbital and 15 to 50 μg per mL for short-acting agents. Other sedative drug ingestions can have an additive effect and result in toxicity at lower doses and blood concentrations [14].

Clinical Manifestations

The most common toxic scenario results from accidental or intentional oral barbiturate overdose. When barbiturates are combined with other sedative medications or alcohol, additive CNS and respiratory depressive effects make overdose more serious. The primary effect is on the CNS, with onset of sedation within 30 minutes. This rapidly progresses to respiratory depression and coma in larger overdoses. Barbiturates suppress the medullary respiratory center and produce respiratory depression [15]. Cardiovascular toxicity can occur after large overdoses. It is caused by direct depression of the medullary centers, direct myocardial suppression, and peripheral vasodilatation. These combine to cause hypotension and cardiovascular collapse. Cardiac dysrhythmias are rare. Hypothermia may result from loss of autonomic function and decrease in overall muscle activity. The gut becomes atonic. Bullous skin lesions (known as “barb blisters”) can occur over pressure points in up to 6% of patients [16]. These are tense bullous lesions containing acellular fluid with detectable amounts of barbiturate. Bullae formation, although common for severe barbiturate poisoning, is not pathognomonic for this poisoning. Bullae formation is also reported in cases of poisoning from other toxicants including carbon monoxide, BZDs, tricyclic antidepressants, phenothiazines, and opioids [17]. Crystalluria is reported following primidone overdose.
Diagnostic Evaluation

Serum phenobarbital concentrations should be measured in poisoning with phenobarbital or primidone. Assay results for detection of other serum barbiturate concentrations are not usually available in a clinically useful timeframe. Other recommended investigations include complete blood cell count, serum electrolytes, renal function studies, creatinine phosphokinase, glucose and liver function tests. An ECG should also be obtained. As barbiturates may be involved in multidrug overdoses, and reliable history may not be available in the case of an unconscious patient, a serum acetaminophen concentration should be measured to exclude occult ingestion. Urinalysis, blood gas analysis, imaging, and lumbar puncture should be considered as clinically indicated.

Management

The mainstay of management following barbiturate overdose is supportive care. Early attention to airway management and ventilation is imperative as up to 40% of patients can develop pulmonary aspiration. Frequent monitoring of vital signs, including temperature, is indicated. Vascular access should be obtained, and the patient should be placed on continuous pulse oximetry and cardiac monitoring. GI decontamination with a dose of activated charcoal (1 g per kg) should be considered in large ingestions in patients with airway protection. Hypotension is initially treated with intravenous crystalloid loading. Because of the multifactorial nature of hypotension, vasopressors or inotropes may be required to treat hypotension unresponsive to fluid challenge. Bedside echocardiography or invasive hemodynamic monitoring can guide choice of vasoactive medications. Hypothermic patients require rewarming.

There is no specific antidote for barbiturate overdose. However, treatments that enhance the elimination of barbiturates should be considered in severe poisoning, with the aim of reducing the duration of coma, requirement for ventilatory support, and reduce cardiovascular instability.

Urinary alkalinization and multidose activated charcoal (MDAC) enhance the elimination of phenobarbital and possibly other barbiturates. In a human volunteer study, MDAC alone was more effective than urinary alkalinization or a combination of the two treatments in decreasing plasma phenobarbital concentrations and reducing plasma half-life. This was associated with greater total body clearance than seen with no treatment [18]. In a joint position statement from the American and European toxicology associations, it was determined that urinary alkalinization could not be recommended as first-line treatment for phenobarbital ingestions as MDAC is more...
effective [19]. In a position statement regarding MDAC, the same organizations recommend that this should be administered when a life-threatening amount of phenobarbital is ingested [7].

Other options for enhanced elimination of barbiturates are extracorporeal methods. In a systematic review of enhanced elimination techniques in barbiturate poisoning, primidone was amenable to enhanced elimination by MDAC. However, despite extracorporeal removal increasing the clearance of short-acting barbiturates to some degree, the clinical utility is limited [20]. The EXTRIP group recommends that extracorporeal treatments be considered for severe long-acting barbiturate poisoning (e.g., phenobarbital) when life-threatening toxicity is present [15]. However, extracorporeal treatments are not as effective in short-acting barbiturate poisoning. The recommended modality is intermittent hemodialysis. If this is not available, then hemoperfusion or continuous renal replacement therapy is the acceptable alternative. Suggested indications for dialysis include prolonged coma, persistent shock despite fluid resuscitation, ongoing toxicity despite MDAC, rising barbiturate concentrations despite MDAC, and if respiratory depression necessitating mechanical ventilation is present. Dialysis should be ceased when there is evidence of clinical improvement. Treating clinicians should be aware of the potential for rebound toxicity, and for precipitation of withdrawal after dialysis in barbiturate-dependent patients [20].

Importantly, following barbiturate poisoning, there is potential for full recovery with good supportive care, despite the presence of prolonged coma, and an isoelectric EEG. Any decision to withdraw care should involve a multidisciplinary approach with input from neurology and toxicology services as available and confirmation that the serum barbiturate concentration is undetectable.
NONBENZODIAZEPINE, NONBARBITURATE SEDATIVE-HYPNOTICS

NBNB sedative-hypnotics include glutethimide (Doriden), ethchlorvynol (Placidyl), meprobamate (Miltown), chloral hydrate (Noctec), and the antispasmodic muscle relaxants carisoprodol (Soma) and baclofen (Lioresal). Toxic effects can be seen from legitimate and illicit use. Newer agents have also been introduced that vary in their toxicity in overdose. These include buspirone, which binds to 5-hydroxytryptamine receptors; zopiclone, a cyclopyrrolole with sedative-hypnotic activity; and zolpidem, which is an imidazopyridine sedative-hypnotic and anxiolytic agent. All of these medications have a high abuse potential secondary to their ability to induce tolerance and dependence.

Chloral Hydrate

Chloral hydrate has been used as a sedative-hypnotic drug since the mid to late nineteenth century. It is still used in pediatric patients for procedural sedation, often in outpatient settings, with ongoing incidence of toxicity and fatality [21]. Chloral hydrate is rapidly absorbed from the GI tract, with onset of action within 30 minutes. It is rapidly metabolized in the liver by alcohol dehydrogenase to the active metabolite trichloroethanol (TCE), which is primarily responsible for its sedative properties. However, alcohol dehydrogenase is inhibited by fomepizole. Increased sedation is seen when chloral hydrate is administered in animal studies suggesting that the parent compound is more sedative than TCE [22]. Chloral hydrate and ethanol influence each other’s metabolism in a number of ways. Chloral hydrate competes with ethanol for alcohol dehydrogenase, thereby prolonging the effect of ethanol. Also, the metabolism of ethanol generates nicotinamide adenine dinucleotide (NADH), which is needed as a cofactor to metabolize chloral hydrate to TCE [23]. TCE is further metabolized, either by glucuronidation to inactive urocholic acid, or by oxidation to trichloroacetic acid, which is also inactive. The elimination half-life of TCE is 4 to 12 hours. Metabolism of TCE changes with age, primarily due to the immaturity of the glucuronidation pathway in neonates. The elimination half-life of TCE is three to four times longer in neonates and infants than it is in older children [23]. This has clinical implications for neonates, especially if chloral hydrate is administered in a multiple dose regimen. It is thought that the metabolism of TCE is saturable at high doses, prolonging elimination further [24].
The usual dose of chloral hydrate in children is 25 to 100 mg per kg. Significant toxicity in children is reported with doses of 1.5 g and survival reported with doses as high as 38 g. For adults, toxicity is seen after more than 2 g, with serious toxicity and death possible with doses greater than 10 g [24]. Survival is reported in adults following ingestion of as much as 70 g, with significant toxicity requiring intensive care support and extracorporeal elimination [25].

Clinical features of toxicity from chloral hydrate overdose develop rapidly following ingestion. Patients may exhibit a characteristic pear-like odor. CNS effects of poisoning manifest as drowsiness, coma, hypothermia and respiratory depression. Pupils may initially be small, but in deep coma, may become dilated. GI effects from mucosal irritation can lead to gastritis, nausea and vomiting with risk of pulmonary aspiration. The most serious manifestation of toxicity is cardiovascular instability. Resistant ventricular tachyarrhythmias are seen and frequently result in death following overdose [24]. Chloral hydrate shortens the refractory period and depresses contractility of the myocardium. There is also an increased sensitivity of the myocardium to catecholamines, a property common to other halogenated hydrocarbons. Dysrhythmias reported include multifocal premature ventricular ectopic beats, supraventricular dysrhythmias, and ventricular dysrhythmias [24,26].

The treatment of chloral hydrate overdose is primarily supportive. All patients with a suspected ingestion should have intravenous access, continuous pulse oximetry, and cardiac monitoring. Hypothermia can be treated with passive rewarming. Activated charcoal (1g per kg) should be administered to patients with significant ingestions and appropriate airway protection. Chloral hydrate is radiopaque, and large ingested amounts may be seen on abdominal radiographs. Airway support and ventilation should be instituted as clinically indicated. Cardiac arrhythmias may not respond to standard antiarrhythmic agents such as lidocaine. β-Blockers, such as propranolol, have been used to successfully terminate refractory arrhythmias [24,27]. A suggested dosage regimen is an intravenous loading dose of 1 to 2 mg propranolol followed by an infusion of 1 to 2 mg per hour [24,27]. Alternatively, in situations/countries where parenteral propranolol is no longer available, a shorter acting agent such as esmolol can be considered. In cases of massive overdose with ongoing coma, refractory arrhythmias, or hypotension, enhanced elimination with hemodialysis and hemoperfusion have been used to clear TCE in particular [25].
Ethchlorvynol

Ethchlorvynol is a hypnotic with muscle relaxant and anticonvulsant activities. Clinical effects are apparent within 15 to 30 minutes, and peak serum concentration is seen in 1 to 2 hours. Ethchlorvynol is highly lipid soluble and is stored in adipose tissue and the brain. It has a unique half-life, being 10 to 25 hours with therapeutic ingestion but up to 100 hours in very large overdoses. Ninety percent of the drug is metabolized by the liver. The patient presents with an altered sensorium ranging from dizziness to facial tingling, giddiness, excitement, dysarthria, ataxia, mydriasis, nystagmus, or areflexia after smaller doses. Severe overdose is characterized by profound and prolonged coma (more than 1 week), hypothermia, respiratory depression, hypotension, and bradycardia. Comatose patients may have an isoelectric electroencephalogram. Seizures are also reported after acute ethchlorvynol ingestion. A sometimes diagnostically useful property of ethchlorvynol is its aromatic and quite pungent odor, described as similar to that of a new car or plastic shower curtain. This may be detected on the patient’s breath.

Overdose treatment is supportive. Hemoperfusion effectively clears the drug. However, redistribution to lipid stores means that repeated hemoperfusion may be necessary because of post-dialysis rebound in serum concentrations.

Glutethimide

The toxic dose of glutethimide is more than 3.0 g, with a usual fatal dose being 10 to 20 g. Glutethimide is highly lipid soluble and displays two-compartment kinetics, with rapid uptake to the brain, followed by systemic distribution. GI glutethimide absorption is erratic, and onset of action is 20 to 30 minutes. Glutethimide is metabolized in the liver to an active metabolite, 4-hydroxy-2-ethyl-2-phenylglutarimide [28], which has a longer duration of action and is more potent than the parent compound [29]. It also stimulates induction of CYP2D6 and has considerable anticholinergic activity.

Signs of acute glutethimide overdose are similar to those seen with barbiturate poisoning. Profound and prolonged coma may result. A unique aspect of acute glutethimide intoxication is a fluctuating level of consciousness [29]. The reason for this is unclear, but theories include enterohepatic recirculation of the parent drug and its metabolites, prolonged absorption of the parent compound from anticholinergic-induced paralytic ileus, and redistribution from adipose stores. Increased intracranial pressure, seizures, areflexia, and muscular twitching may be evident. Hypotension, hypothermia, persistent acidosis, and cardiac arrest have all been reported [29]. The chronic use of glutethimide leads
to tolerance and addiction. The mainstay of treatment for glutethimide poisoning is supportive care. Because there may be a significant anticholinergic-induced delay in gastric emptying, late administration of activated charcoal may be effective. Treatment with MDAC may increase glutethimide and 4-hydroxy-2-ethyl-2-phenylglutarimide elimination because of enterohepatic circulation. Case reports suggest that charcoal hemoperfusion may hasten recovery from coma, but this has never been examined in a controlled fashion [30].

**Carisoprodol and Meprobamate**

Carisoprodol (Soma, Rela) is a congener of meprobamate used as a muscle relaxant. Carisoprodol is metabolized in the liver and excreted in the urine, with an elimination half-life of 4 to 6 hours. Some of the ingested dose is metabolized to meprobamate by CYP2C19. The predominant side effect of the drug is drowsiness. Rarely seen idiosyncratic reactions include asthenia, transient quadriplegia, dizziness, ataxia, diplopia, agitation, confusion, and disorientation. Its toxicity and treatment are otherwise similar to those of meprobamate [31].

Meprobamate (e.g., Equanil, Miltown) is an unusual member of this class of medication. It has antianxiety and muscle-relaxant effects in addition to sedative properties. Meprobamate is available in regular and sustained-release formulations. Toxicity is seen after ingestion of as little as 2 g and fatalities with as little as 12 g [32]. Survival is reported with doses as high as 40 g.

Meprobamate is rapidly and completely absorbed after an oral dose [32]. Peak effect is seen in 3 hours, with a half-life of 10 hours. Most patients feel an effect for up to 36 hours. The drug is largely metabolized in the liver by CYP3A4 and its inactive metabolites are excreted in the urine. Very little of the drug is plasma protein-bound.

The clinical picture of meprobamate poisoning is similar to that of the other medications in this class, with predominately CNS and respiratory function impairment [32]. Hypotension is mediated by a fall in systemic vascular resistance. A persistently elevated serum concentration indicates ongoing drug absorption from bezoar formation. A concentration greater than 2.05 mg per L is associated with CNS depression and coma. Treatment of meprobamate poisoning is similar to that for the other medications in this class. MDAC may be of value after large ingestions because of potential for gastric concretion formation [33]. Hemoperfusion hastens drug clearance and should be considered in patients with cardiovascular compromise or failure to improve despite aggressive supportive treatment.
**Baclofen**

Although usually not considered a sedative or hypnotic drug, baclofen (Lioresal) toxicity mimics that of sedative-hypnotics, and treatment is similar. Baclofen is a synthetic analogue of GABA, and acts as a potent inhibitor of GABA-B neurons, especially in the spine; this has led to it being widely used as an antispasmodic agent to treat various neurologic conditions. Recently, baclofen is increasingly used for the management of alcohol misuse disorders. Baclofen can be administered either orally or intrathecally via programmable implanted infusion pumps, which avoids unwanted systemic side effects.

Following oral ingestion, baclofen is well absorbed from the GI tract, with peak plasma concentration reached within 2 hours. Baclofen is renally eliminated, with only a small portion hepatically transformed. Elimination is by first-order elimination kinetics, with a half-life of 2 to 6 hours after therapeutic dosing.

Baclofen toxicity following intrathecal delivery is predominantly associated with the refilling process, pump programming errors, or problems with dose titration. Overdosing resulting from pump malfunction is less common [34].

Clinical features of toxicity are similar following oral or intrathecal overdose, apart from a latent period following oral ingestion as plasma concentrations reach their peak. Signs include seizures, myoclonus, delirium, altered conscious state, coma, apnea, and hypothermia. Hypotension and hypertension are both reported [35]. Cardiac effects including prolongation of PR and QT intervals, blocked premature atrial contractions, and junctional escape beats may also occur [36]. Bradycardia or tachycardia can occur. Coma can be deep and prolonged for up to a week, with unreactive pupils and near-absent brainstem reflexes, mimicking brain death. Ingested doses of greater than 200 mg are associated with a higher incidence of delirium and coma requiring mechanical ventilation as well as increased hospital length of stay [37].

Management of baclofen toxicity is supportive. It is reasonable to consider the early use of a single dose of 50 g activated charcoal in patients with a protected airway, especially if more than 200 mg baclofen was ingested. Hypotension may respond to intravenous crystalloid bolus. BZDs should be used to control seizures or myoclonus, while being aware that they will contribute to further respiratory or CNS depression. In toxicity caused by intrathecal baclofen misadventure, specific steps may help reduce the drug burden. The specialist physician monitoring the therapy should be alerted as soon as possible, and the pump should be stopped and programming interrogated for errors. Cerebrospinal fluid can be drained, either via lumbar puncture or through the pump.
reservoir. Physostigmine has been used as an antidote for coma in cases of intrathecal baclofen toxicity. Reports of efficacy are mixed and it is not routinely recommended [34]. The baclofen infusion should not be ceased for more than 48 hours, as this may cause damage to the pump system and lead to a withdrawal syndrome [34].

Mechanical ventilation may be required for several days in deeply comatose patients and baclofen intoxication can mimic brain death [37].

**Buspirone**

Buspirone is an anxiolytic drug, which is a partial agonist at serotonin receptors (5-HT$_{1A}$). It also has moderate antagonist effects at central dopamine receptors [38]. It also has central acetylcholine and norepinephrine-mediated effects. The mechanism of action is not completely understood. At low doses, it is predominately anxiolytic, although it may take several weeks to reach this effect. At high doses, it can cause sedation similar to that seen with BZDs (20 mg per day). However, the sedation is much less than that seen with an equivalent dose of the BZD. It is well absorbed orally, and peak serum concentration is seen within an hour. It is hepatically metabolized, undergoing oxidative dealkylation by CYP3A4, with an elimination half-life of 2 to 3 hours.

Adverse drug events reported during therapeutic dosing include weakness, GI distress, dysphoria, headache, and dizziness. It may cause a withdrawal syndrome after prolonged use but does not cross-react with BZDs in treating BZD withdrawal. Flumazenil does not reverse buspirone effect.

Buspirone is not commonly seen in the overdose setting. Serotonin toxicity has rarely been reported when buspirone has been added to therapy in patients prescribed other serotonergic medications [38]. Supportive care is the mainstay of therapy after an overdose.

**Z-Drugs**

**Zopiclone and Eszopiclone**

Zopiclone (Imovane) has a cyclopyrrolone structure, structurally unrelated to BZDs or other sedative-hypnotics. It is available as a racemic mixture of two stereoisomers, one of which, the S-isomer, is marketed in the United States as eszopiclone (Lunesta).

Zopiclone binds to the BZ$_1$ receptor, preferentially acting at the subunits associated with sedation and amnesia. Eszopiclone differs from the racemic mixture in that it has less activity at the receptor subunits responsible for sedation and amnesia, and more affinity for those involved in sleep regulation and anxiolysis [39]. Both zopiclone and
eszopiclone are well absorbed orally, reaching maximal concentration within 1 to 2 hours. They undergo extensive metabolism, primarily by CYP3A4, with active metabolites that are excreted renally. Elimination half-life of zopiclone is 5 to 6 hours [39].

Adverse effects after therapeutic dosing include a bitter taste in the mouth and hangover sedation into the next day, with potential adverse influences on psychomotor performance.

Isolated zopiclone poisoning commonly follows a benign course, with sedation being the predominant feature. Patients with concurrent ethanol or other sedative medication ingestion may develop greater sedation. A report of a series of eszopiclone ingestions reported that the commonest effect was drowsiness, with agitation, ataxia, and tachycardia also occurring [40]. Methemoglobinemia has been noted following overdose of zopiclone. This may be related to oxidative stress caused by an N-oxide metabolite of the parent drug [41].

Management of zopiclone and eszopiclone poisoning is supportive, with attention to airway and respiratory support. In view of the rapid absorption and sedative effects, decontamination with activated charcoal is not indicated. Sedation from zopiclone poisoning may respond to flumazenil [42]. If methemoglobinemia occurs, it should be managed along conventional lines, with administration of supplemental oxygen, and methylene blue if symptoms are significant or methemoglobin concentration is greater than 20%.

Zolpidem

Zolpidem is an imidazopyridine drug and exerts its effects at the BZ1 receptor. It is a potent sedative-hypnotic, with minimal anxiolysis [39]. It is available as both an immediate (IR) and a controlled-release (CR) preparation. After ingestion, the time to maximum concentration is 1 to 2 hours for the IR preparation and 1.5 to 2.5 hours for the CR preparation. It is highly protein bound and metabolized in the liver, predominantly by CYP3A4 to inactive metabolites. Elimination half-life is 2.5 to 3 hours. Zolpidem has displayed zero-order kinetics following overdose in a pediatric patient [43]. Adverse events associated with zolpidem are similar to zopiclone, and include anxiety, dizziness, headache, drowsiness, GI upset, and hangover effects with residual impairment of psychomotor performance after wakening.

Following zolpidem overdose, the most common clinical feature of intoxication is drowsiness. Significant coma and respiratory depression
are unusual [39]. Commonly, symptoms improve within a few hours. Other reported effects include tachycardia, ataxia, slurred speech, vomiting, and hallucinations [44]. The reported effects of poisoning with IR and CR preparations are similar. However, the CR formulation was less likely to cause drowsiness and hallucinations and more likely to result in ataxia [44]. Deaths are reported following overdose of zolpidem in combination with other CNS depressants.

Management of zolpidem intoxication is similar to that of zopiclone and treatment is predominantly supportive. Flumazenil has been used to reverse sedation from zolpidem overdose in adult and pediatric patients [43].

**γ-Hydroxybutyrate**

γ-Hydroxybutyrate (GHB) was initially trialed as an anesthetic induction agent in the 1960s and 1970s. Its adverse effect profile, narrow therapeutic index, and lack of analgesic effects meant that it never gained widespread clinical use [45]. GHB was subsequently found to be a naturally occurring GABA precursor and metabolite in the CNS. It acts as a neuromodulator in the GABA system, and interacts with specific GHB receptors. It has effects on dopamine neurotransmission, and modulates the serotonin and opioid systems. Exogenous sources of GHB can act as a partial agonist at GABA-B receptors and are metabolized to form GABA [46].

GHB is used as a recreational drug. Colloquially it is known as “G,” “Liquid ecstasy,” or “Fantasy,” and became popular for its euphoric, relaxant, and sexual effects. It is also implicated in drug-facilitated sexual assault. Because of rescheduling of GHB in various countries, there has been increasing use of precursor chemicals such as γ-butyrolactone (GBL) and 1,4 butanediol (1,4-BD), which are solvents obtainable from industrial sources. Both are rapidly metabolized to GHB and have similar clinical effects. In a worldwide case of commercial GHB toxicity, children accidentally ingested a brand of toy beads (“Bindeez” or “Aquadots”) that were contaminated with 1,4-BD rather than the intended 1,5-pentanediol. This led to an international recall of the products [47]. The sodium salt of GHB, sodium oxybate (Xyrem), is approved as a treatment for cataplexy associated with narcolepsy in the United States and other countries.

Following oral administration, GHB and its precursors are rapidly absorbed, reaching peak concentration within 30 minutes. GBL is rapidly converted to GHB by serum lactonase. 1,4-BD is metabolized hepatically by alcohol dehydrogenase, then aldehyde dehydrogenase to GHB. This reaction can be inhibited by ethanol and fomepizole [46]. GHB is metabolized in the liver by succinate semialdehyde to succinate, which then enters the Krebs cycle, and is ultimately metabolized to carbon
dioxide and water. Metabolism is saturable at high doses leading to zero-order kinetics initially. A small amount of GHB (2% to 5%) is eliminated unchanged in the urine.

Clinical effects of GHB poisoning occur rapidly after ingestion, and may be potentiated by the effects of alcohol or other drugs. Drowsiness, euphoria, hallucinations, delirium, nausea, vomiting, and mild hypothermia are seen. Myoclonic jerks and seizure-like activity may occur. Pupils are commonly small. Doses of greater than 50 mg per kg lead to coma and respiratory depression [46]. Cardiovascular effects include bradycardia and hypotension. Recovery from coma is typically rapid, with return of conscious state occurring within a few hours of ingestion. Deaths have been reported, either due to drug ingestion itself or occurring as a result of misadventure while intoxicated, both with GHB in isolation, or in combination with other drugs of abuse. In a series of GHB-related deaths, the most common cause of death was prehospital cardiorespiratory arrest [45]. Chronic use can lead to tolerance and physical dependence, and there is a well-documented withdrawal syndrome comprising anxiety, agitation, hallucinations, paranoia, tachycardia, and hypertension. This can occur rapidly following abstinence from the last dose, even within a matter of hours [46].

Management of GHB overdose is supportive. Airway protection and ventilatory support are the mainstays of treatment. Prolonged sedation may indicate co-ingestion of other sedative drugs. Because of the expected short period of unconsciousness and expected rapid recovery, practice regarding the necessity of intubation is variable, depending on experience within centers. In a study comparing conservative airway management to intubation between two tertiary referral hospitals in the same city, it was found that intubation was associated with a greater emergency department length of stay and increased likelihood of hospital admission [48]. Because GHB is usually ingested in liquid form, and rapid deterioration in conscious state can be expected, GI decontamination with activated charcoal is not indicated. There is no specific antidote for GHB poisoning, but various agents have been investigated. Physostigmine, flumazenil, and naloxone do not reverse sedation following GHB use in humans, and are not recommended [46].

Hemodialysis has been used to successfully treat severe acidemia in a patient following a massive (600 mL) GBL ingestion [49]. It is theorized that the rapid metabolism of large quantities GBL to GHB by plasma lactonase resulted in dissociation of the GHB ($pK_a$ 4.72) to its anion and hydrogen ions, producing the severe acidosis in this case. In most cases, the ingested dose is not as large as in this one and rapid endogenous clearance results in a short duration of symptoms. Importantly, hemodialysis was not used to enhance GBL or GHB elimination in this case, only to treat the marked acidemia.
REFERENCES

Few topics in medicine are as steeped in controversy and anecdotal treatment recommendations as the field of toxicology. Fortunately, the toll of human suffering that venomous creatures exact in developed countries is relatively low. In developing nations, however, life-threatening encounters with venomous snakes and scorpions are more common. This chapter offers guidance for the evaluation and management of bites and stings of venomous snakes, spiders, and scorpions indigenous to North America (Table 124.1). Although the general principles of management of envenomations outlined here may be applicable to other regions of the world, specific approaches, such as indications for and types and doses of antivenoms, vary by region, and local experts should be consulted for advice.

- Mild envenomation with progression OR moderate-to-severe envenomation (evidence of systemic toxicity [systemic signs or symptoms, or laboratory abnormalities])—administer antivenom (see text)
- Shock management includes IV physiologic saline boluses (10–20 mL/kg) and high-dose antivenom; if refractory, consider albumin and, as last resort, vasopressors
- Blood products uncommonly required after administration of adequate antivenom (always give antivenom first)
- Opioids as needed for pain control
- If concerned re: compartment syndrome, measure intracompartmental pressures (see text); fasciotomy only for documented increase in pressures unresponsive to elevation of the extremity and antivenom (with or without a trial of mannitol)
- Antibiotics only for evidence of secondary infection (uncommon)

**Coral snake**

**Texas or Eastern coral snake (Micrurus spp)**
- ABCs, O₂, cardiac/pulse oximetry monitoring, at least one large-bore IV line, physiologic saline infusion
- Early intubation and respiratory support if any evidence of difficulty with breathing or handling secretions
- Update tetanus immunization status as needed
- No evidence of envenomation—admit for monitoring (minimum of 24 h)
- Evidence of neurotoxicity—administer antivenom if available (see text); if no antivenom available, supportive care only; admit for monitoring until recovered

**Sonoran coral snake (Micruroides euryxanthus)**
- ABCs, O₂, cardiac/pulse oximetry monitoring, at least one large-bore IV line, physiologic saline infusion
- Update tetanus immunization status as needed
- No evidence of envenomation—admit for monitoring (minimum of 24 h)
- Evidence of neurotoxicity—admit for monitoring until

• Antivenom (see text)  
• Update tetanus immunization status as needed |
| Nonneurotoxic scorpion          |  
• Analgesics as needed  
• Update tetanus immunization status as needed |

These are guidelines only and do not replace individual physician judgment. Consultation with an expert toxicologist or poison control center specialist may be helpful.  
ABCs, airway, breathing, circulation assessment and management as needed; O₂, oxygen; IV, intravenous; MRSA, methicillin-resistant Staphylococcus aureus.
SNAKE ENVENOMATION

All of the terrestrial American venomous snakes belong to one of two families: Viperidae (subfamily Crotalinae, or pit vipers) and Elapidae (or coral snakes). Venomous snakes are native to every state of the United States except Alaska, Hawaii, Maine, and Rhode Island.

Pit Viper Envenomation

The vast majority of venomous snakebites in North America are inflicted by pit vipers, which include the rattlesnakes (genera *Crotalus* and *Sistrurus*), and the cottonmouth water moccasins, copperheads, and cantils (*Agkistrodon* spp). These snakes possess paired, pitlike heat receptors (foveal organs) on the anterolateral aspects of the head. These receptors aid the snake in aiming its strike and determining the quantity of venom to be injected [1].

Pit viper venoms contain numerous enzymatic components and a number of nonenzymatic, low-molecular-weight polypeptides. Venom compositions vary not only from species to species, but from snake to snake within a species, and even in an individual snake depending on its age, size, health, and other factors [1]. In general, the most serious envenomations in North America are caused by the rattlesnakes (particularly *Crotalus* spp), with cottonmouth water moccasin (*Agkistrodon piscivorus* spp) bites being less severe and copperhead (*A. contortrix* spp) bites causing predominantly local findings with little serious systemic toxicity.

The major enzymes in pit viper venoms include hyaluronidase (spreading factor), phospholipase A (responsible for cell membrane disruption), and various proteases (causing local tissue destruction) [1]. Venom metalloproteinases, termed *disintegrins*, result in disruption of vascular integrity [2]. Despite the impressive toxicity of such enzymes, the nonenzymatic, low-molecular-weight polypeptide fractions appear to be up to 20 times more lethal, on a weight-for-weight basis, than crude venom [3]. The toxicity of pit viper venom is enhanced by release of various autopharmacologic compounds from damaged tissue (e.g., histamine, bradykinin, and serotonin) [1].

Clinical Manifestations

Envenomated patients typically experience moderate-to-severe pain at
the bite site within 5 to 10 minutes. The pain is often described as burning and may radiate along the bitten extremity. Swelling at the bite site, often associated with ecchymosis, soon follows and may progress along the entire extremity within hours. Rapid lymphatic absorption of venom may lead to impressive, early lymphangitis and regional adenopathy.

Within the first 24 to 36 hours, vesicles and hemorrhagic bullae may develop at the bite site and along the bitten extremity. These are less common in bites treated early with adequate amounts of antivenom [1,3]. Petechiae or purpura may also be present.

Systemic manifestations of pit viper envenomation can involve virtually any organ system. Nausea and vomiting are common and may appear early with severe bites [3]. Weakness, diaphoresis, fever and chills, dizziness, and syncope may also occur [1]. Some patients experience a minty, rubbery, or metallic taste in their mouth [1,3]. Muscle fasciculations (myokymia) or paresthesias of the scalp, face, tongue, or digits indicate a moderate-to-severe envenomation. Systemic coagulopathy can lead to bleeding at any anatomic site, including the gastrointestinal, respiratory, genitourinary, and central nervous systems, although clinically significant bleeding is uncommon following bites in North America [3].

Alterations in heart rate and blood pressure may occur. Early hypotension is usually caused by pooling of blood in the pulmonary and splanchnic vascular beds, whereas delayed shock results from blood loss, third spacing of intravascular volume, and hemolysis [1,4]. Pulmonary edema can occur in severe envenomations, and is secondary to disruption of pulmonary vasculature intimal linings and pooling of pulmonary blood [5].

Multifactorial renal failure may occur, but is uncommon. Contributing factors include hypotension; hemoglobin, myoglobin, and fibrin deposition in renal tubules; and direct venom nephrotoxicity [3].

Muscle weakness may be seen after bites by some rattlesnakes such as the eastern diamondback rattlesnake (Crotalus adamanteus) and some specimens of the Mohave rattlesnake (Crotalus scutulatus) [5,6] that possess phospholipase A2 neurotoxins in their venoms. Although neuromuscular respiratory failure is rare, it can occur in severe bites. Respiratory distress may also occur because of respiratory muscle fasciculations and incoordination, pulmonary edema, or anaphylactic reactions to venom or antivenom [3].

Snake venoms do not appear to cross the blood–brain barrier to any significant extent, and rare findings such as seizures and coma are secondary to hypotension, hypoxia, or intracranial bleeding. In rare cases, prothrombotic venom components can cause cerebral infarcts [7].
Diagnostic Evaluation

Important aspects of the history include details of the incident (such as type and size of snake if known, time and number of bites, and methods of first aid applied) and the patient’s medical history (including any prior snakebites, medications, allergies, and tetanus immunization status).

Pit viper envenomation is a true medical emergency with potential for multisystem involvement, and the treating clinician must maintain vigilance for onset or progression of signs and symptoms. Although approximately 20% of bites by US pit vipers result in no envenomation (“dry bites”) [8], in some cases where envenomation has occurred, onset of toxicity may be delayed for hours and severity can then progress rapidly. Consultation with an authority in the area of toxicology such as a regional poison control center specialist is prudent.

Puncture-wound patterns can be misleading in the diagnosis of snakebite. Occasionally, there is only a single puncture wound or many tiny punctures [9]. A dry bite may or may not have fang puncture marks, but there is no more pain than would be expected from simple puncture wounds. Envenomation is confirmed by the presence of local tissue effects (particularly progressive swelling as assessed by serial measurements of limb circumference; see Table 124.1), systemic effects, and/or laboratory abnormalities.

Essential laboratory studies include a complete blood cell count, serum electrolytes, blood urea nitrogen, creatinine, creatine phosphokinase, prothrombin time or international normalized ratio, fibrinogen, fibrin degradation products, and urine analysis. Blood for type and screening should also be sent for evaluation as soon as possible because direct venom effects and antivenom effects may interfere with this process later. Obtain a chest radiograph, an arterial blood gas, and an electrocardiogram as clinically indicated.

Occasionally, the history and diagnosis may be unclear, especially in children. When patients present without having seen a snake and have no findings other than puncture wounds and mild pain, the differential diagnosis includes a dry bite, bite by other animal or arthropod (e.g., nonvenomous snake, centipede, or spider), and mechanical puncture wounds (e.g., cactus spines). Persistent oozing of blood that should have coagulated from puncture wounds suggests the presence of coagulopathy and should heighten suspicion of pit viper bite in this clinical context.

Management

First-aid efforts are best limited to reassuring the victim, immobilizing and splinting the extremity at the level of the heart, and transporting as quickly as possible to a hospital. Previously recommended first-aid
measures including incision, suction, constriction bands, pressure immobilization, tourniquets, packing of the extremity in ice, or application of electric shocks should be avoided because they are ineffective and may result in further complications \([9,10,11]\).

Initial management should focus on any derangements of the patient’s airway, breathing, or circulation. Cardiac, blood pressure, and pulse oximetry monitoring should be in place. Two large-bore intravenous (IV) lines infusing normal saline are started, preferably in sites other than the bitten extremity, and blood work is sent to the laboratory. Any devices applied in the field in an attempt to limit venom spread should be temporarily left in place until an IV line is established.

Management of significant pit viper envenomation centers on the judicious use of an appropriate antivenom. In North America, antivenom therapy is indicated for victims with progressive local tissue findings or systemic abnormalities (significant systemic symptoms or signs, or laboratory abnormalities [e.g., paresthesias, hypotension, prolongation of prothrombin time or international normalized ratio, hypofibrinogenemia, or thrombocytopenia]) (see Fig. 124.1). Controversy exists, however, on the use of antivenom for copperhead (\(A.\ contortrix\)) bites presenting with progressive soft-tissue swelling in the absence of systemic abnormalities. Given that most such bites do well with conservative therapy alone, the risk versus benefit of giving antivenom in these cases is currently unclear and is being investigated \([12]\). Again, consultation with a toxicology expert is prudent in such cases.

**FIGURE 124.1** Guidelines for beginning antivenom therapy for victims of pit viper bite in the United States (see text for details). \(^a\)Keep extremity at heart level, being careful to differentiate redistribution of edema (with changing limb position) from progression of severity of swelling. \(^b\)Repeat normal lab work every hour for 4 to 6 hours until AV is started or the decision is made that AV is not necessary (i.e., the
Antivenom Administration

If possible, informed consent should be obtained before antivenom administration. Antivenom should be administered in a closely monitored setting. Epinephrine and endotracheal intubation equipment should be immediately available at the bedside during initial antivenom administration, and a physician should be available to manage any acute adverse drug effects that may develop.

In the United States, at the time of this writing, there is currently a single commercially available antivenom for pit viper bites—CroFab Crotalidae Polyvalent Immune Fab, Ovine (BTG International Inc., West Conshohocken, PA) (FabAV). This antiserum contains pooled, purified Fab immunoglobulin fragments from sheep immunized with one of four different pit viper venoms. It comes in a lyophilized state and is effective against all North American pit vipers.

Antivenom should be started as soon as possible after the indication for administration is apparent. Although there are no defined endpoints in terms of time or dosage for when to withhold antivenom, antivenom is beneficial for treating only findings directly related to continued presence of unbound, circulating venom (e.g., ongoing coagulopathy). It is ineffective in reversing end-organ damage that has resulted from prior venom effects (e.g., renal failure). The efficacy of antivenom in preventing local wound necrosis is limited, because it cannot reverse local cellular damage once it has been initiated by rapidly acting venom enzymes and nonenzymatic polypeptides [13]. Any ability to reduce necrosis depends on early administration.

Dosing of FabAV is based not on age or size of the patient, but rather on the potential venom load delivered to the victim. As children generally receive similar quantities of venom in a bite as adults do, pediatric dosing is the same as for adults. The starting dose is four to six vials for patients with signs or symptoms of systemic toxicity or evidence of progressive local venom effects. In victims with hypotension or severe bleeding, the starting dose should be increased to 8 to 12 vials [14]. Each vial should be reconstituted with 18 to 25 mL of warm sterile water or saline and the vials gently agitated (vigorous shaking of the vials may cause development of foam, resulting in less delivered protective antibody fragments). The total dose to be administered is diluted in 250 mL of normal saline and infused over 1 hour (starting slowly at the onset of
infusion and gradually increasing the rate). During the first hour after the dose is completed, the patient is monitored for further progression of local effects and systemic symptoms, and laboratory studies are rechecked. The starting dose of FabAV is repeated if venom effects continue to progress. This pattern is continued until the patient stabilizes. Coagulation studies may not normalize after the initial dose, because time is required for repletion of coagulation factors after venom neutralization, but there should be evidence of improvement [15,16]. After stabilization, two vials of FabAV are administered every 6 hours for three additional doses to prevent recurrence of venom toxicity. Further doses may be needed at the physician’s discretion depending on the patient’s clinical picture.

Adverse effects of antivenoms, as heterologous serum products, are divided into three major groups: acute allergic and nonallergic anaphylaxis, and delayed serum sickness. Acute reactions most commonly manifest with urticaria, although bronchospasm, hypotension, and angioedema can also occur [17]. Serum sickness is characterized by pruritus, fever, arthralgias, lymphadenopathy, and malaise, which can occur 1 to 2 weeks after antivenom therapy [18]. The incidence of acute reactions to CroFab is approximately 8%, and serum sickness occurs in approximately 13% of patients [19]. Management of acute reactions centers on rapid diagnosis, temporarily halting the infusion and treating with epinephrine, antihistamines, and steroids (see Chapter 69). Generally, once the reaction is controlled, the antivenom infusion can be restarted, possibly in a more dilute state and at a slower rate. Serum sickness is relatively benign and easily treated with steroids, antihistamines, and nonsteroidal anti-inflammatory drugs until symptoms resolve. Most cases do well with oral prednisone (1 to 2 mg/kg/d) until symptoms resolve, followed by a taper over another week.

**Supportive Measures**

Venom-induced hypotension should be treated with antivenom and volume expansion. If organ perfusion fails to respond promptly with crystalloid infusion (1 to 2 L in an adult and 20 to 40 mL per kg in a child), administration of albumin may be considered [1,7]. Vasoactive amines may be required after adequate volume resuscitation of refractory cases [1].

Although pit viper envenomation can result in significant coagulopathies, the incidence of clinically significant bleeding in the United States is low [20]. Management of coagulopathy in patients with evidence of major bleeding may require administration of packed red blood cells, platelets, fresh-frozen plasma, and/or cryoprecipitate [1,21]. There is limited experience using recombinant factor VIIa for severe
coagulopathy following rattlesnake bite [22]. It is important to begin antivenom therapy before the infusion of such products to avoid augmenting the consumptive coagulopathy.

Therapy to prevent acute renal failure includes ensuring adequate hydration and monitoring urinary output. If renal failure occurs, dialysis may be required, although it does not remove circulating venom components [1,3].

Although steroids are useful in the management of adverse reactions to antivenom (see previous discussion), there is no role for them in the primary management of snake envenomation.

**Wound Care and Surgery**

Wound care begins with cleaning the bite site with a suitable germicidal solution and covering it with a dry, sterile dressing. As soon as antivenom, if indicated, has been started, the extremity should be elevated in a well-padded splint in a position of function with cotton between the digits [1]. Antibiotics are unnecessary unless field management involved incisions into the bite site [23] or the wound appears clinically infected. Tetanus immunization status should be updated as necessary.

Intact hemorrhagic blebs and bullae should be protected. If ruptured, they should be unroofed after any attendant coagulopathy has been reversed, and managed with wet to dry dressings [3]. Wound debridement may be necessary if there is significant tissue necrosis. The use of hyperbaric oxygen therapy to treat these wounds has yet to be fully studied [1,24]. Physical therapy is an important part of the care plan for returning the extremity to its pre-envenomation functional capacity.

The role of surgery in the primary management of pit viper envenomation is very limited. The speed with which snake venom is absorbed makes routine excision of the bite site fruitless, and routine exploration of the site does little to mitigate systemic effects of venom, may worsen the overall outcome by adding surgical trauma, and can prolong hospitalization [1].

The incidence of compartment syndrome after snake envenomation appears low despite the frequently impressive local findings of bitten extremities [25]. Myonecrosis that occurs is usually caused by direct venom effects and rarely vascular compromise from elevated intracompartmental pressures [25]. In combined series of nearly 2,000 victims of pit viper envenomation, only four patients required
fasciotomy; each of these patients received inappropriate ice treatment or inadequate antivenom therapy [25]. If there is concern about an impending compartment syndrome, intracompartmental pressures should be checked using any standard technique. If pressures exceed 30 to 40 mm Hg and remain elevated for more than 1 hour despite treatment with antivenom, limb elevation, and possibly mannitol infusion (1 to 2 g per kg in a normotensive patient), fasciotomy may be required [26]. While some evidence suggests that fasciotomy may actually worsen local myonecrosis [27], unabated elevation of intracompartmental pressures can have disastrous effects, such as debilitating neuropathy [28], and fasciotomy may still be required. Whenever possible, informed consent should be obtained before proceeding with fasciotomy.

**Disposition and Outcome**

Patients with apparent dry bites can be discharged from the emergency department if they remain asymptomatic with normal laboratory values (repeated prior to discharge) and vital signs after 8 hours of observation [29]. The envenomated patient can be discharged from the hospital when all venom effects have begun to resolve and when antivenom therapy is complete, which is usually within 48 hours after admission. At the time of discharge, every patient should have appropriate follow-up arranged for continued wound care and physical therapy, and should be warned about the symptoms of serum sickness. If such symptoms occur, the patient should seek medical care promptly.

Venom-induced coagulopathy and thrombocytopenia may recur anytime up to 14 days after the last dose of antivenom [30], and fatal intracranial bleeding and other cases of major delayed bleeding have been reported [31,32]. Patients should be followed closely after discharge from the hospital with repeat complete blood count and coagulation studies at 2 to 3 days and 3 to 5 days after the last dose of FabAV, and they should be warned to avoid elective procedures and risky activities (such as contact sports) for at least 2 weeks [14]. If on follow-up there is evidence of clinically significant bleeding, if the laboratory coagulopathy is worsening or severe (i.e., platelet count <25,000 per mm$^3$, INR >3, aPTT >50 seconds, fibrinogen <50 mg per dL, or multicomponent coagulopathy), or if the patient has an underlying condition that makes him prone to bleeding or engages in activities that make him prone to trauma, additional antivenom can be considered, although its efficacy at reversing delayed recurrence of coagulopathy is reduced [15,16,30,33].

The historical mortality rate for patients treated with antivenom in the United States was 0.28%, compared with 2.61% for patients not receiving antivenom [34]. The impact of FabAV on mortality rates remains to be determined. Death after pit viper poisoning is most likely to occur 6 to 48
hours after envenomation [34]. Fewer than 17% of deaths occur within 6
hours and fewer than 4% within 1 hour [34]. The major reasons for poor
outcomes in pit viper envenomation are delay in presentation, inadequate
fluid resuscitation, inappropriate use of vasopressors, and delay in
administration or inadequate dosing of antivenom [35]. The incidence of
upper-extremity functional disability after pit viper envenomation is at
least 32% [36], and may be higher when careful, objective functional
measurements are obtained [37].

**Coral Snake Envenomation**

There are fewer than 100 coral snake bites reported in the United States
each year [38]. The US coral snakes include the eastern coral snake
(*Micrurus fulvius*), the Texas coral snake (*Micrurus tener*), and the
Sonoran coral snake (*Micruroides euryxanthus*). Mexico boasts 15
*Micrurus* species as well as the Sonoran coral snake [39]. Coral snakes
lack the foveal organs of pit vipers. Owing to their much less effective
venom-delivery mechanism (small fangs fixed in an upright position on
the anterior maxillae), only approximately 40% of coral snake bites result
in envenomation [1,40], although it has been estimated that one large
coral snake is capable of delivering enough venom to kill four to five
humans [41]. In the United States, it appears that the severity of
envenomation tends to be greatest with the eastern coral snake (*M.
fulvius*), less with the Texas coral snake (*M. tener*), and least with the
Sonoran coral snake (*Micruroides euryxanthus*) [1,42].

**Clinical Manifestations**

Coral snake venoms are primarily neurotoxic. Low-molecular-weight
polypeptides in the venom are capable of inducing nondepolarizing,
postsynaptic blockade at neuromuscular junctions [43]. There are few
local findings at the bite site, and the onset of systemic symptoms may be
delayed for many hours [40,44]. Fang marks may be small and difficult to
detect [45], with variable pain and little swelling at the site [44]. The
patient may experience local paresthesias that may radiate proximally
and be associated with muscle fasciculations [44]. The earliest systemic
findings may include alteration of mental status [46]. Nausea and
vomiting may occur, along with increased salivation [40]. Bulbar-type
paralysis can occur as early as 90 minutes after the bite and progress to
peripheral paralysis [1]. Findings may include extraocular muscle paresis,
ptosis, pinpoint pupils, dysphagia, dysphonia, slurred speech, and
laryngeal spasm [40,44]. Death from coral snake envenomation has been
reported because of respiratory failure or cardiovascular collapse [1].
Diagnostic Evaluation

The important history is similar to that obtained from victims of pit viper bites. In areas where coral snakes coexist with harmless coral snake mimics, such as milk snakes (*Lampropeltis* spp), it is helpful if the color pattern of the offending snake can be reliably obtained or, better yet, if the victim can produce a digital photo of the offending reptile. The differential diagnosis of coral snake envenomation is usually limited to bites by other brightly colored, nonvenomous snakes. Native US coral snakes can be identified by a characteristic red, yellow, and black banding pattern, with the red and yellow bands contiguous (“red on yellow, kill a fellow; red on black, venom lack”) and the bands completely encircling the body. In the harmless coral snake mimics, the red and yellow bands are separated by black bands, and the bands do not completely encircle the body. This color pattern does not, however, reliably identify coral snakes south of Mexico City [47]. The remainder of the differential diagnosis is the same as for pit vipers.

Management

Rapid transportation to a hospital is of utmost priority following coral snake bites. In Australia, where all native venomous snakes are elapid relatives of the coral snake, a potentially beneficial first-aid intervention is use of a pressure-immobilization wrap. In this technique, the entire bitten extremity is firmly wrapped with an elastic or crepe bandage and splinted [48]. The wrap is applied snugly—as tightly as for a sprained ankle [48]—and it is important that the extremity be kept as immobile as possible and the patient carried to medical care [49]. One small animal study has demonstrated apparent benefit of the technique in prolonging survival following coral snake venom injection [50].

As with pit viper bites, attention is initially directed to the patient’s airway, breathing, and circulatory status. Supplemental oxygen should be administered, cardiac and pulse oximetry monitoring established, and at least one IV line should be started. Impending respiratory failure is suggested by cyanosis, trismus, laryngeal or pharyngeal spasm, increased salivation, or any sign of cranial nerve paralysis [44]. If any of these findings is present, prophylactic intubation is indicated to prevent aspiration. Once the airway and respiratory status are addressed, a more complete physical examination is performed. Any swelling should be documented and observed for progression.
Antivenom Therapy

As with most venomous snakebites, definitive management of significant *Micrurus* bites should center on the use of appropriate antivenom. Production of the only Food and Drug Administration (FDA)–approved antivenom for coral snake bites in the United States, Antivenin (*Micrurus fulvius*) (Wyeth Laboratories Inc., Marietta, PA), has been discontinued by the manufacturer. At the time of this writing, the FDA has extended the expiration date on the single remaining lot of this antivenom until January 31, 2018. It is possible that Pfizer, Inc. may resume coral snake antivenom production for the United States at some point or that ongoing research into the use of an alternative foreign-produced antivenom for US coral snake bites may lead to approval of another product. (Updates on this topic can be obtained by contacting regional poison control centers.) If an effective coral snake antivenom is available, it should be administered in a monitored setting (with epinephrine available), in consultation with an expert in snake venom poisoning, and with informed consent if possible. Administer antivenom to any patient clearly bitten by an eastern coral snake (*Micrurus fulvius*) specimen, even in the absence of signs or symptoms, because once signs or symptoms appear, it may be difficult to reverse or halt their progression [40,44]. This is likely unnecessary if the offending snake was a Texas coral snake (*M. tener*) [42]. There is no antivenom for the Sonoran coral snake (*Micruroides euryxanthus*), but the venom of this snake is much less toxic, and there have been no reported deaths after its bite [1,46]. Management of any coral snake bite, in the absence of available antivenom, is entirely supportive. Airway protection and ventilatory support may be required for days following *Micrurus* bites [44], but with modern intensive care, the prognosis should be good.

Wound Care

The wounds from a coral snake bite should be washed with a germicidal solution and tetanus prophylaxis updated as necessary. Prophylactic antibiotics are not indicated.

Disposition and Outcome

All patients with potential coral snake bites should be admitted to an intensive care unit for at least 24 hours for close monitoring regardless of symptoms or antivenom requirement [51]. The projected case-fatality rate in untreated cases is up to 10% [40]. Total resolution of all signs or symptoms (e.g., weakness) may take several weeks [44].
Exotic (Imported) Snake Envenomation

Exotic venomous snakes are commonly kept in zoos, museums, and sometimes by private individuals in “underground zoos.” Occasionally, they may be inadvertently found in imported goods and produce. If a patient has been bitten by an exotic venomous snake, every effort should be made to definitively identify the reptile. This can be done by contacting available zoo personnel or herpetologists. The treating physician should then call a regional poison control center for assistance (1-800-222-1222). These centers have access to a national listing of available sources of exotic antivenoms in stock in the United States. Antivenoms tend to be quite specific for the species against which they protect, and should be used only if there is clear evidence of their efficacy against the offending species. Sound supportive care, combined with an appropriate antivenom when available, should offer the best chances of an optimal outcome.
SPIDER ENVENOMATION

Although many spiders are capable of biting humans, only two types in North America are medically significant in that they have the potential to cause significant sequelae and possibly death: the widow spiders (*Latrodectus* spp) and the recluse spiders (*Loxosceles* spp).

Widow Spider Envenomation

Of five known species of widow spider in the United States, the black widows (*Latrodectus mactans*, *L. hesperus*, and *L. variolus*) are the best known [52]. The female black widow is dark black and oval shaped, with a characteristic, typically hourglass-shaped, ventral red, orange, or yellow marking on the abdomen. The body is approximately 1.5 cm long with a leg span up to 4 cm. The other two species in the United States are the red-legged widow or red widow (*L. bishopi*) and the brown widow (*L. geometricus*) [52]. Widow spiders are found in all of the 48 contiguous states and Hawaii [53], and are responsible for most of the exceedingly rare spider-related deaths in North America. Only the female is dangerous to humans; the male, a nondescript and much smaller brown spider, is incapable of delivering a bite through human skin.

The venom of all species of widow spiders is similar in composition and toxic effects. The most deleterious venom component is alpha-latrotoxin, a potent neurotoxin that acts primarily at the neuromuscular junction [54]. The venom initially stimulates the release of neurotransmitters (acetylcholine, epinephrine, and norepinephrine) and then blocks neurotransmission by depleting synaptic vesicles [55,56]. It does not cause dermonecrosis or hemolysis [57].

Clinical Manifestations

The widow spider’s bite may be unnoticed by the patient or may be felt as a sharp sting [55]. The bite site may be visible, with tiny fang marks approximately 1 mm apart, and the area may be slightly warm and blanched with a surrounding erythematous, indurated zone [58]. Swelling is minimal [59].

Significant symptoms usually appear 10 minutes to 2 hours after envenomation [58]. The most prominent symptom is pain. It begins at
the bite site as a dull ache and spreads first to local muscle groups and then to larger regional muscle groups of the abdomen, back, chest, pelvis, and lower extremities. Muscle spasms and rigidity are classically present [58,60,61]. Spasms of abdominal musculature can mimic an acute abdomen, although rebound tenderness is absent. Chest muscle rigidity may produce respiratory distress [60,61]. The respiratory rate increases, and there may be associated tachycardia and hypertension. Pain severity typically peaks after several hours [62]. In patients at risk, the hypertension can lead to cerebrovascular accidents, exacerbation of congestive heart failure, and myocardial ischemia [55]. Cardiac dysrhythmias and priapism have been reported, and there are extremely rare cases of myocarditis [58,63].

Associated signs or symptoms include diaphoresis (local or diffuse; possibly asymmetrical), fever, headache, nausea and vomiting, restlessness and anxiety, periorbital edema, and skin rash [58,60,64]. Deep tendon reflexes may be increased [61].

Diagnostic Evaluation

The history surrounding a widow spider bite is confusing if a spider was not seen. A high index of suspicion should be maintained in patients presenting with compatible complaints. It is important to obtain a medical history, such as hypertension, pregnancy status, allergies, and tetanus immunization status. The physical examination entails a general screening with particular attention to the vital signs, which should be checked at frequent intervals. Close examination for a bite site may be productive.

There are no diagnostic changes in routine laboratory tests in widow spider envenomation. An elevation in white blood cell count and serum creatine phosphokinase values may be seen [65], and proteinuria has been reported [66]. An electrocardiogram and chest radiograph should be obtained as clinically indicated. A pregnancy test should be obtained in women of childbearing age because widow spider venom is a potent abortifacient.

The differential diagnosis includes envenomations by other arthropods, such as neurotoxic scorpions (see “Scorpion Envenomation” section), and systemic disorders, such as sympathomimetic overdose, acute rhabdomyolysis, heat cramps, heat stroke, neuroleptic malignant syndrome, tetanus, and strychnine poisoning. Other causes of abdominal pain and rigidity should be considered.

Management

Although there are no specific first-aid measures effective in widow
spider bites, temporary application of ice to the bite site may reduce pain. Adequate airway, respiration, and circulatory status should be ensured. After instituting oxygen, cardiac and pulse oximetry monitoring, and starting an IV line, attention should be directed to alleviating painful muscle spasms using a cautious combination of benzodiazepines and opioids [52], although analgesia may prove difficult to achieve [67]. Calcium gluconate and other muscle relaxants such as methocarbamol are not consistently effective.

Hypertension usually responds to bed rest, muscle relaxants, analgesics, and sedation [54]. Specific antihypertensive agents can be used if necessary [54].

**Antivenom**

A specific, equine, whole-immunoglobulin widow spider antivenom available in the United States, Antivenin (*Latrodectus mactans*) (Black Widow Spider Antivenin) (manufactured by Merck & Co., Inc., West Point, PA), appears, in vitro, to be able to bind all *Latrodectus* venoms, regardless of species [68]. Indications for antivenom use in *Latrodectus* envenomations remain controversial, however, given recent evidence that questions its efficacy in relieving pain or reversing systemic toxicity [67] as well as its small but real risk of adverse reactions (see below). Antivenom might be considered in patients who are severely envenomated, pregnant, or in labor, or in those who have a history of cardiovascular disease or other major medical problems and evidence of significant envenomation despite benzodiazepine and opioid therapy [58,61,62]. Assistance from an expert toxicologist or poison center is helpful in making the decision about whether to administer antivenom.

If antivenom is to be given, informed consent should be obtained, and the patient should be in a monitored setting with epinephrine available at the bedside. Consideration can be given to premedicating with IV antihistamines (H\textsubscript{1} and H\textsubscript{2} blockers), although the benefit of such an approach is unproven. The antivenom can be given intravenously (one reconstituted vial further diluted in 50 to 100 mL of normal saline, administered over 30 minutes) or intramuscularly (IM) (one reconstituted vial in the anterolateral thigh) [69], with the physician in immediate attendance to observe for any sign of adverse drug events. Although studies suggest that there is no clinical benefit to administering *Latrodectus* antivenom IV over IM [68], the IV route may be best if the patient is in shock or younger than 12 years old [69]. The dosage is the same for children [54,60]. One vial is generally given initially, but a second vial can be administered if deemed necessary [60,62]. Signs or symptoms should completely resolve within a few hours of antivenom administration [60,62].
The types of adverse drug events seen with widow spider antivenom are the same as for snake antivenoms, with acute reactions occurring in approximately 2% and serum sickness in approximately 10% [64]. Deaths due to acute reactions have occurred following administration of widow spider antivenom [65,70]; this, plus questions of efficacy should limit its use to cases that are truly severe and potentially life threatening. It is hoped that ongoing research into a new F(ab’)2 widow spider antivenom might demonstrate improved efficacy with less risk, resulting in a safe, clearly effective antivenom use for widow spider bites in North America [71].

The clinical course of most patients with widow spider envenomation is benign [58,72], but significant pain and spasms can persist for 2 to 3 days [62]. Most healthy adults do well with supportive measures and adequate administration of parenteral benzodiazepines and opioids [58].

Disposition and Outcome

Patients can be discharged from the hospital when signs or symptoms of envenomation have been significantly controlled, although it may be best to admit and observe younger children. Patients should be given analgesics and muscle relaxants, prescribed bed rest, and instructed to return if they worsen. The mortality rate from widow spider envenomation in the United States is much less than 1% [55,58], and it is debatable if there are truly deaths from envenomation. Recovery from widow spider envenomation may sometimes be slow, with weakness, fatigue, paresthesias, headache, and insomnia persisting for several months [54].

Recluse Spider Envenomation

Of the approximately 13 species of recluse spider (Loxosceles spp) found in the United States [73], the brown recluse (Loxosceles reclusa) is best known [74]. All species are characterized by a violin-shaped marking on the dorsal aspect of the cephalothorax (though this may be hard to see in some specimens) and three pairs of eyes, in contrast to the four pairs found in most spiders. The adult body is 10 to 15 mm long and the legs span 2 to 3 cm. Both the male and female spiders are dangerous [62].

The brown recluse is found throughout the southern, south-central, and midwestern United States; other species are found in the western part of the country [52]. While recluse spiders may cause severe dermonecrosis (necrotic arachnidism), the majority of bites actually
result in insignificant lesions [75].

The venoms of the different species of recluse spider have similar toxic effects [76]. They contain a number of different proteins, most of which demonstrate enzymatic activity [77]. Sphingomyelinase D is likely responsible for the venom’s cytotoxic and hemolytic effects [78,79]. Venom activation of the complement cascade induces a series of autopharmacologic changes that amplify toxicity to a variable degree in victims [80].

The cutaneous changes seen after a recluse spider bite are initiated by venom-induced endothelial damage in small dermal vessels that become occluded with microthrombi, producing vascular stasis and infarction [81]. Polymorphonuclear leukocytes are attracted to the site via a chemotactic response and propagate the inflammatory, necrotic reaction [81,82]. Accumulation of polymorphonuclear leukocytes at the site appears to be a vital component of the dermonecrotic response and is related to complement activation [82].

Clinical Manifestations

The clinical course of recluse spider envenomation varies from a mild temporary irritation at the bite site to a rare, severe, potentially fatal outcome [74]. The bite is occasionally felt as a mild stinging sensation, although it may go completely unnoticed. During the next several hours, there may be pruritus, tingling, mild swelling, and redness or blanching at the bite site [83]. Variable degrees of local pain and tenderness due to local vasospasm and ischemia occur within 2 to 8 hours [83,84]. At 12 to 18 hours, a small central vesicle (clear or hemorrhagic) often develops at the site and is surrounded by an irregular zone of erythema or ecchymosis and edema, which may have a distinct gravitational distribution around the central lesion [85]. The vesicle ruptures, and the erythema gives way to violaceous discoloration [84]. In 5 to 7 days, the bite site undergoes aseptic necrosis (i.e., dry, gangrenous slough), with the center becoming depressed below the normal level of the skin, and a black eschar forms. The eschar later sloughs, leaving an open ulcer that heals in weeks to months [84]. Bites to fatty regions of the body tend to be more severe, with undermining of the skin and more extensive scarring [84]. Necrosis rarely involves deeper structures such as nerves, muscles, tendons, or ligaments [86]. Lesions destined to develop significant necrosis usually demonstrate early evidence of local ischemia [83].

Systemic (viscerocutaneous) loxoscelism is rare, but can be rapidly progressive and severe, particularly in children [62]. Systemic symptoms generally start 24 to 72 hours after the bite and occasionally occur before cutaneous findings become impressive [87]. Symptoms are often flulike,
with fever, chills, headache, malaise, weakness, nausea and vomiting, myalgias, and arthralgias [84]. Hemolytic anemia with hemoglobinemia, hemoglobinuria, jaundice, thrombocytopenia, disseminated intravascular coagulation, acute renal failure, seizures, and coma have been reported [62]. The severity of systemic symptoms is directly related to the quantity of venom deposited, but does not necessarily correlate with the severity of cutaneous changes [85].

**Diagnostic Evaluation**

It is uncommon for a victim of a *Loxosceles* bite to see the offending spider because the bite is relatively painless, and, given that the spider is nocturnal, a large percentage of bites occur while the victim is asleep [75]. As the spider is rarely available for identification, determining the cause of early lesions is difficult [85], and the diagnosis of spider bite is usually presumptive. The working diagnosis should be cutaneous necrosis if the precise cause is unknown and necrotic arachnidism if a biting spider was seen but not identified.

An examination for evidence of systemic loxoscelism should be performed. The severity of any lesion present should be assessed and any evidence of secondary infection noted. There are no characteristic changes in routine laboratory tests in recluse spider envenomation. In patients with severe envenomation, laboratory studies should include a complete blood cell count and urinalysis [84]. If there is any evidence of consumptive coagulopathy, hemolysis, or hemoglobinuria, further studies should include prothrombin time and partial thromboplastin time, electrolytes, blood urea nitrogen, and creatinine, and a specimen should be sent for blood typing and screening. The white blood cell count may be as high as 20,000 to 30,000 per mm$^3$, and the hemoglobin may fall to as low as 4 g per dL [57,62,84]. Serial complete blood cell counts and urinalyses should be obtained in patients with significant lesions or systemic loxoscelism [84].

There is no commercially available test to definitively diagnose recluse spider envenomation. The differential diagnosis for *Loxosceles* envenomation includes bites or stings by other arthropods (e.g., other spiders, ticks, scorpions, ants, fleas, kissing bugs, bedbugs, and biting flies), superficial skin infections (especially methicillin-resistant *Staphylococcus aureus*), cutaneous anthrax, diabetic ulcers, plant puncture wounds, sporotrichosis, toxic epidermal necrolysis, pyoderma gangrenosum, erythema nodosum, erythema migrans, herpes zoster, herpes simplex, erythema multiforme, purpura fulminans, and contact dermatitis.
Management

No commercial antivenoms exist for *Loxosceles* bites in the United States. The majority of cases require only local wound care, including cleansing of the bite site, application of a sterile dressing, immobilization with a well-padded splint, and tetanus prophylaxis as necessary [57]. Frequent local application of ice or cold packs during the first 72 hours to reduce sphingomyelinase D activity may be beneficial [74]. If an ulcer develops, it should be cleaned several times each day with hydrogen peroxide or povidone–iodine solution [84]. Pruritus can be treated with antihistamines. Antibiotics to prevent secondary cellulitis can be considered [74] and should include coverage for methicillin-resistant *S. aureus* when evidence of secondary infection is present [88].

It is important to emphasize to patients that nothing has been proven to decrease the extent of dermonecrosis after these bites and that most lesions heal quite satisfactorily with conservative management alone [57,84]. Controversial modalities for managing the wound include the use of steroids, dapsone, colchicine, surgery, hyperbaric oxygen therapy, and topical nitroglycerine application [77,89–92]. Routine use of these agents should be avoided until prospective controlled studies prove that benefits outweigh risks.

Early excision of the wound site is contraindicated because it is impossible to predict the ultimate extent and severity of the lesion [77]. Severe-appearing lesions commonly involute and regress spontaneously to leave minimal defects [93]. Surgical procedures that might be required, such as skin grafting, should be postponed at least 6 to 8 weeks to ensure that the necrotic process has been completed and to improve chances of healing [77]. Hyperbaric oxygen therapy may be useful in particularly severe wounds if it is easily and readily available, but this remains unproven [77].

Initial management of systemic loxoscelism includes adequate hydration, maintaining electrolyte balance, and administering nonsalicylate antipyretics and analgesics [57,84]. Although the use of systemic corticosteroids to stabilize red blood cell membranes has yet to be studied in a controlled fashion, an early, short course of therapy may be beneficial in patients with hemolysis. The recommended dose is 1 mg/kg/d of prednisone orally for 2 to 4 days [57]. Blood products are used as indicated to treat anemia or thrombocytopenia [57]. If hemoglobinuria occurs, hydration becomes critically important, and urine output should be maintained at 2 to 3 mL/kg/h [84]. If renal failure
develops, dialysis may be indicated \([57,84]\), and dialysis does not remove venom or hemoglobin from the circulation \([84]\). Therapeutic plasma exchange may have a role in refractory hemolysis \([94,95]\).

**Disposition and Outcome**

Any patient with suspected systemic loxoscelism should be admitted to the hospital and have frequent (every 1 to 6 hour) hemoglobin measurements to detect the onset of any hemolysis. Young children who cannot tolerate frequent blood draws should have their urine monitored for free hemoglobin \([96]\). Patients with isolated cutaneous involvement should have frequent outpatient wound checks until the wound is clearly healing.

Occasionally wounds caused by recluse spiders can be disfiguring and debilitating, requiring surgical repair and revision, but most heal well with conservative therapy alone. Although there have been no reports of deaths in patients bitten by positively identified recluse spiders in the United States \([62,84]\), there is potential for death from systemic loxoscelism, especially in children.
Although there are at least 40 species of scorpions found in the United States, only one, the bark scorpion (Centruroides sculpturatus [formerly C. exilicauda]), is sufficiently toxic to be medically significant [97]. All other US species cause only mild, local envenomation without neurotoxicity. The bark scorpion is found throughout Arizona with isolated colonies located in surrounding counties of bordering states (Nevada, Texas, New Mexico, and California). Other closely related Centruroides scorpions of medical importance are found in Mexico. The bark scorpion is 13 to 75 mm long and yellow-brown in color, with variable striping on the dorsum [98], and has a small subaculear tubercle at the base of the stinger.

The venom of C. sculpturatus is complex. It contains at least five distinct neurotoxins that cause release of neurotransmitters from the autonomic nervous system and adrenal medulla and stimulate depolarization of neuromuscular junctions [99,100]. Its venom contains no major enzymatic components [101].

**Clinical Manifestations**

Although most C. sculpturatus stings are minor, envenomation may be severe, especially in children. In the largest series of bark scorpion stings in children, the mean onset of symptoms was 20 minutes (range 0 to 130 minutes) [102]. There is usually intense pain, which may extend beyond the site and be associated with paresthesias. Local signs, such as swelling or bruising, are uncommon following bark scorpion stings [101].

Systemic findings may include fever, motor hyperactivity, opsoclonus, tachycardia, hypersalivation, hypertension, vomiting, respiratory distress, hypoxemia, stridor and diaphoresis, and, in patients treated without antivenom, almost one-fourth will require intubation and mechanical ventilation [102].

Clinical findings after envenomation by other US scorpions (nonneurotoxic) consist of immediate, brief, intense pain, mild soft-tissue swelling, and mild ecchymosis [103]. Systemic manifestations are uncommon, and allergic reactions are rare [104].

**Diagnostic Evaluation**

Adults and older children stung by scorpions frequently see the offending organism and can give a reliable history. In younger children, the history may be unclear, and the clinical picture after a bark scorpion sting may be
confused with another diagnosis such as central nervous system infection, widow spider envenomation, tetanus, dystonic drug reaction, intoxication (e.g., pesticides, anticholinergics, sympathomimetics, xanthines, propoxyphene, and strychnine), drug withdrawal, anaphylaxis, or seizure disorder. A general medical history should be obtained, symptoms assessed, and prehospital treatments noted. Vital signs should be frequently monitored. The sting site should be inspected and the patient examined for signs of systemic toxicity. Table 124.2 is a useful grading scale for determining severity of bark scorpion stings [102].

<table>
<thead>
<tr>
<th>Severity</th>
<th>Description</th>
</tr>
</thead>
</table>
| Mild Envenomation | I: local pain &/or paresthesias at sting site  
II: pain &/or paresthesias remote from sting site |
| Severe Envenomation | III: Either cranial nerve or neuromuscular dysfunction  
IV: Cranial nerve and neuromuscular dysfunction |
| Cranial nerve dysfunction: tongue fasciculations, hypersalivation, slurred speech, or opsoclonus  
Neuromuscular dysfunction: involuntary shaking and jerking of the extremities. |

There are currently no commercial laboratory tests of diagnostic benefit in patients suspected of C. sculpturatus envenomation. The white blood cell count and serum glucose may be elevated [99]. Increases in serum amylase, creatine phosphokinase, and renal function studies, mild abnormalities in coagulation parameters, and cerebral spinal fluid pleocytosis have been reported [102,105]. No labs are necessary for victims of nonneurotoxic scorpion stings.

Management
The majority of *C. sculpturatus* stings, particularly in adults, can be treated with cold compresses and analgesics, usually at home [99]. Adults with more severe envenomations and young children should be managed in a hospital. These patients should receive oxygen and have an IV line established, along with continuous cardiac and pulse oximetry monitoring. The key to managing significant *C. sculpturatus* stings is the administration of antivenom (see below). The airway should be secured if there are signs of respiratory failure or inability to handle secretions [105]. Pain, anxiety, restlessness, muscular hyperactivity, and hypertension can initially be treated with parenteral opioids and benzodiazepines while antivenom is readied [102]. It is rare for specific antihypertensive agents to be required, especially after antivenom is given.

**Antivenom**

In 2011, the FDA approved the first antivenom (Anascorp; Instituto Bioclon, Mexico City, Mexico) for managing bark scorpion stings in children or adults [102]. Anascorp is an equine, F(ab′)2 product that has been shown to rapidly reverse systemic toxicity following *C. sculpturatus* envenomation. It is indicated in any patient with significant toxicity following bark scorpion sting. The starting dose (in children and adults) is 3 vials; however, it is reasonable to start with a single vial and repeat until symptoms are resolved. Each vial of lyophilized antiserum is reconstituted using 5 mL of normal saline, and the contents are placed in a 50 mL volume of normal saline. With the patient closely monitored, the entire dose is given intravenously over 10 minutes. The patient is then observed for 30 to 60 minutes. If symptoms fail to resolve, further antivenom is given in one vial aliquots (again diluted in 50 mL of normal saline and administered over 10 minutes). This sequence is repeated until symptoms improve. Most patients experience symptom resolution within 4 hours and can be discharged at that time [97].

Although bark scorpions historically caused more direct venom toxicity deaths in Arizona than any other venomous creatures [102], deaths are now exceptionally rare [98,99], but the potential for a fatal outcome should not be underestimated, especially in small children and the infirm.
CONCLUSION

The key to managing an envenomation victim, regardless of the offending organism, is to be alert for signs or symptoms suggesting worsening toxicity, and to be ready to intervene quickly when indicated. At times, that intervention may involve administration of a specific antidote such as antivenom, but more often it involves providing sound supportive care according to the tenets of critical care medicine.
REFERENCES

This is a list of therapeutic agents that are used in medical toxicology, and has been organized into a Table format to facilitate rapid access to concise information guiding indication and dosing of a therapeutic agent. The table is divided into four columns. The first column is alphabetically organized in terms of a specific agent; individual agents appear alphabetically in the Index. The second column focuses on indications and uses in medical toxicology. The third column provides guidelines for dosing of the therapeutic agent. The fourth column highlights caveats and potential complications. The content of this table is not intended to be a comprehensive list of therapeutic agents and is not a substitute for reference textbooks in medical toxicology (e.g., Goldfrank Toxicologic Emergencies and Medical Toxicology) and does not address envenomations by exotic venomous creatures or envenomations outside the United States. Some of the listed therapeutic agents may not be available to every clinician, and it may be prudent to be familiar with the therapeutic agents that are available in the respective clinician’s practice.

### Antivenom

**Known or suspected scorpion (Centruroides sp.) envenomation**

- **Centruroides**
  - **IV Anascorp**: Administer 3 vials (adults or pediatrics); closely monitor for resolution of clinically important signs of envenoming during and up to 60 min following antivenom infusion; administer additional antivenom, if needed, one vial every 30–60 min and monitor for resolution of clinically important signs of envenomating during and up to 60 min following antivenom infusion.
  - Reconstitute each Anascorp vial with normal saline 5 mL and mix by continuous gentle swirling; dilute total dose to be administered in normal saline 50 mL and infuse over 10 min.

### Atropine

**Cholinesterase inhibitors** (e.g., organophosphorus agents, nerve agents)

- IV atropine 1–4 mg; double the dose every 5–10 min as needed until pulmonary secretions are controlled (tachycardia not a contraindication to atropine); once stabilized, start atropine infusion (10%–20% of total dose for stabilization per hour); restart atropine at the first signs of cholinergic excess; administer with pralidoxime (see Pralidoxime).

### Botulism antitoxin heptavalent (A, B, C, D, E, F, G)—BAT

**Botulism**

- **BAT**, equine-derived botulinum toxin type naturally occurring available from state or Centers for Disease Prevention (CDC).

</tbody>
</table>
repeated doses over 12–24 h.

OR

- Administer 40 mL of 2.5% calcium gluconate solution by Bier block technique (i.e., catheterize a distal vein and exsanguniate extremity by elevation and compression with an esmarch bandage, inflate blood pressure cuff to 100 mm Hg above systolic pressure and maintain for 15–20 min following calcium administration, gradually deflate cuff over 5 min).

- Symptomatic inhalation exposure

  Nebulized calcium 2.5% solution in normal saline may improve symptoms following mild exposure.

- History suggestive of a substantive dermal or oral exposure that may lead to systemic toxicity

  Oral calcium or magnesium antacids 30–60 mL

  IV calcium chloride with normal vital signs and hemodynamic stability should be administered; serum calcium concentrations should be monitored every 30 min for the first 2–3 h; IV calcium chloride 1 g boluses to maintain serum calcium concentration in the high normal laboratory reference range, repeat as needed; a fall in serum calcium concentration below the normal range, dysrhythmias or a fall in blood pressure is treated with IV calcium chloride 2–3 g boluses every 15 min.

<p>| Carboxypeptidase-G2 (glucarpidase) | Methotrexate (MTX) overdose or serum MTX concentration &gt;1 µmol/L with delayed MTX clearance due to renal dysfunction. | (2 h after leucovorin carboxypeptidase-G2 (CPDG2) 50 U/kg over 5 min; a second 50 U/kg dose may be administered 48 h later; leucovorin within 2 h before or after a CPDG2 dose; leucovorin is a CPDG2 substrate (see Folinic acid and Sodium bicarbonate). Intrathecal CPDG2 2,000 U in 12 mL normal saline over 5 min. |</p>

**Chelators**

- Dimercaprol (BAL, British Anti-Lewisite)
- Edetate calcium disodium (CaNa$_2$EDTA, calcium disodium versenate)
- Deferoxamine (DFO)
- Diethylenetriaminepentaacetate (DTPA)
- Prussian blue (ferric hexacyanoferrate)
- 2,3-Dimercaptosuccinic acid (DMSA, Succimer)

**Arsenic (As): suspected acute symptomatic As poisoning**

IM BAL 3–5 mg/kg every 4 h tapering to every 12 h over several days; switch to DMSA 10 mg/kg every 8 h for 5 days, reduced to every 12 h for another 2 weeks; additional course of treatment may be considered based on post-treatment results: 24-h urinary As excretion <25 µg/period when urinary inorganic As concentration <200 µg/L.

**Lead (Pb)**

- Symptomatic Pb encephalopathy

IM BAL 75 mg/m$^2$ (3–5 mg/kg) every 4 h have elapsed since the priming dose of BAL start IV CaNa$_2$EDTA 1,500 mg/m$^2$/d. In cases of cerebral edema and/or increased intracranial pressure associated with encephalopathy, administer CaNa$_2$EDTA (same dosage) by deep IM injection (extremely painful) along with procaine 0.5% in two to three divided doses every 8–12 h. Continue BAL and CaNa$_2$EDTA days. Cessation of chelation is often followed by a rebound in blood Pb concentration, a second chelation course based on whole Pb concentration after 2 days’ interruption of CaNa$_2$EDTA treatment and the persistence or recurrence of symptoms. A third course may be required if the
rebounds ≥50 µg/dL after the third last dose.

- Symptomatic patients who are not overtly encephalopathic
  IM BAL 50 mg/m² (2–3 mg/kg) every 4 h have elapsed since BAL, start IV CaNa₂EDTA (30 mg/kg/d) or in 12 h. BAL and CaNa₂EDTA continued for 5 d if whole blood Pb level is not discontinued any time during these 5 d. A second or third course may be considered based on previous paragraph.

- Asymptomatic patients with whole blood Pb levels ≥70 µg/dL
  BAL and CaNa₂EDTA same doses and same guidelines as for symptomatic patients without encephalopathy. CaNa₂EDTA chelation may be necessary if whole blood Pb concentration rebounds ≥50 µg/dL after chelation has ceased. A second course of treatment whole blood Pb concentration may be necessary if whole blood Pb concentration rebounds ≥50 µg/dL after chelation has ceased. An interval ≥2 wk assess extent of post-treatment rebound in whole blood Pb concentration.

Mercury (Hg)
- Elemental Hg poisoning
  Oral DMSA (10 mg/kg every 12 h for 2 wks) oral DMSA (10 mg/kg every 12 h over the course of treatment) until urinary Hg excretion approaches background. An interval ≥2 wk may be indicated to assess extent of post-treatment rebound in whole blood Pb concentration.
• Suspected acute inorganic Hg poisoning: BAL and DMSA (see Organic Hg poisoning).

• Organic Hg poisoning: DMSA appears promising in animal studies (see Elemental Hg).

**Chelators**

Iron (Fe) poisoning:
- Symptomatic patient (e.g., recurrent vomiting or diarrhea, acidosis, shock and decreased level of consciousness or coma) regardless of serum Fe concentration or asymptomatic patient with serum Fe concentration ≥500 μg/dL (90 μmol/L).
- IV DFO initiated slowly and gradually increased to 15 mg/kg/h over 20–30 min and continued for 24 h; therapy >24 h (rarely needed) is interrupted for 12 of every 24 h; treatment endpoints include resolution of systemic signs/symptoms, correction of acidosis, and return of urine color to normal (if the patient developed vin rosé colored urine during therapy).

Known or suspected internal contamination with radioactive cesium (Cs) or radioactive/nonradioactive thallium (Tl):
- Adults/adolescents: Oral Prussian blue 3 g t.i.d., Peds (2–12 yrs): 1 g t.i.d.; treatment for 30 d minimum and reassess patient for residual whole body radioactivity, treatment duration guided by level of contamination and clinical judgment.

Radioactive cesium (Cs) or radioactive/nonradioactive thallium (Tl).
Known or suspected internal contamination with plutonium, americium, or curium.

Day 1: IV calcium-DTPA (CaDTPA) 1 g (Peds 14 mg/kg, max 1 g) in 100–250 mL D5W, normal saline, or LR over 30 min.

Day 2: IV zinc-DTPA (ZnDTPA) 1 g (Peds 14 mg/kg, max 1 g) in 5 mL over 3–4 min 100–250 mL D5W, normal saline, or LR over 30 min every day (continue with daily CaDTPA dosing if ZnDTPA not available); treatment duration based on individual response and weekly radioactivity in blood, urine, and fecal samples.

Internal plutonium, americium, or curium contamination by inhalation.

Day 1: Nebulize diluted CaDTPA 1 g (Peds 14 mg/kg, max 1 g) at a 1:1 ratio with sterile water or saline.

Day 2: Nebulize diluted ZnDTPA 1 g (Peds 14 mg/kg, max 1 g) at a 1:1 ratio with sterile water or saline; after nebulization, encourage individuals not to swallow any expectorant; treatment duration based on individual response and weekly radioactivity in blood, urine, and fecal samples.

As many as 20% of hospitalized adult patients in most medical settings may have a history of an alcohol-related condition [1]. In recent surveys, as many as 14% of Americans experience an alcohol use disorder during their lifetime [2]. Anticipation and recognition of early signs of sedative–hypnotic withdrawal of the sedative–hypnotic abuser allow timely treatment and prevent the development of serious withdrawal consequences, such as seizures, hyperthermia, delirium, and death. The management of withdrawal syndromes from γ-hydroxybutyrate (GHB) and baclofen may be particularly challenging. Recognition and treatment of the less life-threatening signs and symptoms of opioid withdrawal avoid unnecessary investigation of the frequently severe gastrointestinal symptoms and make the patient more comfortable and able to cooperate. Because ethanol and other sedative–hypnotic withdrawal may have life-threatening consequences, the patients with signs of significant withdrawal should be admitted to the intensive care unit (ICU) for the stabilization and monitoring. In addition, drug-dependent patients admitted to the ICU for the management of other serious medical or surgical problems may subsequently enter withdrawal in this substance-free environment [3].

Clinical withdrawal implies the presence of physical tolerance and dependency. Factors contributing to the development of dependency include dose of the drug, duration of effect, frequency of administration, and duration of abuse. Shorter-acting drugs require more frequent administration to produce dependency and are associated with more acute and severe withdrawal symptoms than longer-acting drugs. *Tolerance* is defined as a decreased physiologic response elicited by a given dose of the drug. The patient who chronically ingests a large amount of ethanol may not be sedated by a dose that would render a nondrinker comatose. A heroin abuser who has been drug-free during a year’s imprisonment may suffer fatal respiratory depression from a dose of heroin that previously would have provided only mild sedation. This physiologic tolerance to drug effect that occurs with chronic use may arise
from changes in drug metabolism, such as induction of one or cytochrome P450 enzymes and changes in drug affect at the cellular level. Cross-tolerance occurs when the chronic ingestion of one substance decreases the response to a second substance. Cross-dependency allows one drug to be substituted for another to alleviate or prevent withdrawal symptoms. Ethanol, barbiturates, and nonbarbiturate sedative–hypnotic agents are cross-tolerant and cross-dependent with one another but not with other sedating drugs such as opioids, neuroleptics, or antihistamines. These factors have important therapeutic implications.

**ETHANOL WITHDRAWAL**

**Pathophysiology**

Ethanol produces its toxic effects (relaxation, euphoria, disinhibition, slurred speech, ataxia, sedation, stupor, coma, and respiratory depression (see Chapter 99); through modulation of a variety of neurotransmitters and ion channels [4]. It acts, in part, by interacting with the γ-aminobutyric acid (GABA\(_A\)) receptor complex, potentiating inhibitory GABA-ergic receptor function by inducing chloride flux through the chloride channels of the receptor complex. Ethanol also inhibits excitatory N-methyl-d-aspartate (NMDA) glutamate receptor function, contributing to impaired cognition and blackouts associated with chronic ethanol use [5]. Inhibition of NMDA receptor function changes intracellular calcium levels and, as a result, affects cell-signaling cascades, including phosphorylation [5]. Other neurotransmitter systems affected by ethanol include dopamine and serotonin [6]. Ethanol has been found to affect 5-hydroxytryptamine receptor function by increasing the potency with which agonists bind this receptor [4]. Ethanol consumption may also result in an increase in endogenous opiates, particularly with respect to ligands for the kappa opioid receptor, contributing to its euphoric effect [7]. Although it was not recognized until the 1950s that delirium was a manifestation of ethanol withdrawal rather than toxicity, the hallmarks of ethanol and other sedative–hypnotic intoxication are distinctly different from the manifestations of withdrawal from these agents [8,9].

Ethanol withdrawal produces a hyperadrenergic state characterized by intense sympathetic nervous system activation. This may be due in part to compensatory central nervous system (CNS) mechanisms that counteract the depressant effects of ethanol intoxication. During withdrawal, these compensatory mechanisms are unopposed, resulting in increased neural stimulation [10]. In support of this theory, elevated levels of plasma and urinary catecholamines have been associated with tachycardia, elevated blood pressure, and tremors observed in
withdrawing patients. A decrease in the inhibitory activity of presynaptic α₂-receptors has been demonstrated and may explain, in part, the increase in norepinephrine levels. In addition, an increase in β-adrenergic receptors during withdrawal has been demonstrated. One study showed an increase in plasma levels of the dopamine metabolite homovanillic acid in patients presenting with delirium tremens [11].

Compensatory changes in number and function of inhibitory GABA_A receptors and excitatory NMDA glutamate receptors during chronic ethanol use may contribute to the CNS stimulation brought on by the cessation of ethanol. The abrupt withdrawal of the GABA-potentiating effects of ethanol leads to a disinhibition of neural pathways in the CNS [6]. During withdrawal, ethanol’s enhancing effect on chloride flux is lost, resulting in a decrease in GABA-ergic function. Tachycardia, diaphoresis, tremors, anxiety, and seizures have been associated with this reduction in GABA-induced chloride flux [6]. Upregulation in NMDA glutamate receptors and changes in their receptor subunit composition increases calcium flux through these receptors [12]. This likely contributes to the excitotoxic neuronal cell death associated with ethanol withdrawal [13]. Repeated episodes of withdrawal increase the propensity for ethanol withdrawal seizures through altered GABA_A and NMDA receptor function [6]. Because NMDA receptors mediate dopaminergic transmission, the increased NMDA receptor function that occurs during withdrawal may also lead to decreased dopaminergic and serotonergic transmission, contributing to alcohol craving [5].

Ethanol withdrawal occurs when a dependent patient suddenly stops drinking or drinks at a slower rate than previously. In either case, a significant drop in the serum ethanol level occurs. In chronic alcoholics, signs of withdrawal are commonly present even when their serum ethanol concentrations are higher than 100 mg per dL [14]. The patients admitted to the ICU with ethanol withdrawal often have a significant underlying disease that has led to an inability to maintain an ethanol intake adequate to prevent withdrawal. Alcoholic gastritis, hepatitis, pancreatitis, and pneumonia commonly precipitate decreased ethanol use and withdrawal. These patients typically present to the hospital after 24 to 48 hours of abdominal pain or fever and may be tremulous or have had a withdrawal seizure. Another type of ICU patient prone to withdrawal is one who has continued to imbibe ethanol nearly to the moment of arrival at the hospital. Intoxicated patients are prone to experience traumatic events and arrive in the operating room, recovery room, or ICU still
intoxicated. A history of ethanol abuse or previous withdrawal may not be available in the postoperative or intubated patient when initial signs of withdrawal occur. Failure to recognize ethanol withdrawal in the seriously ill or injured patient may lead to prolonged complications [2,15].

Clinical Manifestations

Ethanol withdrawal results in a variety of signs and symptoms that vary in severity and duration. In their landmark article, Victor and Adams [9] described withdrawal as a tremulous–hallucinating–epileptic–delirious state. Although this description is often used to divide ethanol withdrawal syndrome into four stages, it is important to remember that the various manifestations of ethanol withdrawal form a progressive continuum of severity. The patient in ethanol withdrawal may exhibit one or more of these manifestations. The sequence of clinical events may be inconsistent. The severity of the withdrawal is often dose-dependent, with more severe reactions associated with heavier and longer periods of drinking [14].

Tremulousness and seizures are the most common clinical manifestations of ethanol withdrawal. They tend to occur early and are generally considered mild-to-moderate ethanol withdrawal symptoms. Delirium tremens is a late manifestation of ethanol withdrawal and constitutes the most serious clinical presentation. Although dramatic and life-threatening, delirium tremens is but one aspect of ethanol withdrawal and affects 5% of withdrawal patients [1,6].

Mild ethanol withdrawal is usually characterized by a period of acute tremulousness (the “shakes”). It begins 6 to 8 hours after a reduction in ethanol intake [1,6,16]. The patients usually complain of tremulousness, nausea, vomiting, anorexia, anxiety, and insomnia. Physical examination reveals an evidence of mild CNS and autonomic hyperactivity, which includes tachycardia, mild hypertension, hyperreflexia, irritability, and a resting tremor. Occasionally, significant tremor may not be appreciated despite the patient’s complaint of feeling “shaky inside.” Despite the fact that the patients in delirium tremens have evidence of significant disorientation, this milder form of withdrawal is characterized by a clear sensorium, although the patient may have a minor disorientation to time. Symptoms of mild ethanol withdrawal usually peak between 24 and 36 hours, and 75% to 80% of these patients recover uneventfully in a few days. Approximately 20% to 25% of the patients presenting with mild ethanol withdrawal progress to serious withdrawal manifestations, which include seizures, hallucinations, or delirium tremens. A few studies have attempted to identify predictors of deterioration, and a correlation with the amount of regular alcohol consumption, elevated blood alcohol concentration at the time of admission, and an age over 40 years has
been demonstrated, at least in a trauma population [17]. Additionally, thrombocytopenia, hypokalemia, and elevated homocysteine levels may indicate increased risk for the development of delirium tremens, though they may represent markers of the degree of regular alcohol consumption rather than independent determining factors [2,18]. It remains impossible to reliably predict which the patients will deteriorate [14].

Seizures that occur among alcoholics may or may not be due to ethanol withdrawal. Although ethanol withdrawal accounts for many of these seizures, other common causes include pre-existing idiopathic and post-traumatic epilepsy [8,9,18]. Other complications of ethanol abuse not necessarily associated with withdrawal, such as hypoglycemia, hypomagnesemia, and hyponatremia, may also precipitate seizure activity [18]. Ethanol intoxication itself is not thought to be proconvulsant. Alcoholic patients with a history of epilepsy appear to have a greater incidence of seizures than those without a pre-existing seizure disorder. Failure to comply with anticonvulsant regimens may, in part, account for this. Brief abstinence (even overnight) may also lower the seizure threshold sufficiently to provoke seizures in susceptible patients. Because management strategies differ depending on whether the patient has a history of seizure disorder unrelated to ethanol withdrawal, differentiating between them becomes important [19].

Early studies showed that as many as 25% to 33% of the patients with ethanol withdrawal demonstrate seizure activity [8,9]. Most ethanol withdrawal seizures (rum fits) occur between 6 and 48 hours after cessation or relative abstinence from drinking [6,16]. Mild-to-moderate signs of withdrawal may precede the seizures, or the seizure may herald the onset of ethanol withdrawal. They are short, generalized, tonic–clonic seizures, 40% of which are limited to a single isolated event. Often a short burst of two to six seizures with normal sensorium between seizures occurs over a few hours. The patients with ethanol withdrawal seizures usually have normal baseline electroencephalograms, in contrast to those with underlying seizure disorders. Status epilepticus or recurrent seizure activity lasting longer than 6 hours is distinctly uncommon in ethanol withdrawal and suggests another diagnosis.

Ethanol-related seizures may foreshadow the development of delirium tremens. In one series of the patients with ethanol withdrawal seizures, delirium tremens developed in 35% [18]. In some patients, postictal confusion blends imperceptibly into delirium tremens. As many as 40% of the patients in whom delirium tremens subsequently developed exhibited an initial clearing of their postictal state followed by the onset of delirium tremens 12 hours to 5 days later [16].
Disordered perceptions characterized by hallucinations and nightmares were noted in 25% of tremulous patients in early withdrawal by Victor and Adams [9]. The hallucinations were predominantly visual in nature, auditory only in 20% of the cases, and rarely tactile or olfactory. Commonly described visual phenomena in this setting may include the graphic depiction of bugs crawling on the walls or bed.

A subset of hallucinating patients does not demonstrate tremulousness or other signs of sympathetic hyperactivity, known as acute alcoholic hallucinosis, this uncommon clinical presentation (occurring in 2% of the patients of Victor and Adams) is a distinct manifestation of ethanol withdrawal that usually begins within 8 to 48 hours of cessation of drinking [9]. It is characterized by disabling auditory hallucinations, often of a persecutory nature. These patients display no evidence of formal thought disorder, have no personal or family history of schizophrenia, and are usually oriented to person and place. In most cases, symptoms last for 1 to 6 days, although they may persist for months and come to resemble chronic paranoid schizophrenia. These symptoms usually respond to therapy with cross-tolerant agents such as benzodiazepines.

Delirium tremens is characterized by a significant alteration of sensorium associated with dramatic autonomic and CNS hyperactivity. Only 5% of the patients who exhibit any of the previously discussed manifestations of ethanol withdrawal progress to delirium tremens. Delirium tremens appears to be more common among the patients with a history of significant withdrawal and a long history of ethanol use. The patients for whom delirium tremens develops may not have demonstrated earlier signs of withdrawal. Other patients who have had ethanol withdrawal seizures or hallucinations may deceptively improve before the onset of delirium tremens, which is rarely seen before 48 to 72 hours after cessation or reduction in drinking and may be delayed for as long as 5 to 14 days [6,9]. These patients are truly delirious, exhibiting disorientation, global confusion, hallucinations, and delusions. Speech is unintelligible. Psychomotor disturbances, such as picking at bedclothes, significant restlessness, and agitation, are common and often require the use of physical restraints. Autonomic disturbances, such as tachycardia, hypertension, tachypnea, hyperpyrexia, diaphoresis, and mydriasis, are present. Cardiac dysrhythmias may also occur [20]. Seizures rarely occur during delirium tremens. Concomitant illness, trauma, seizures, or therapeutic drugs may mask or modify the typical presentation.

Mortality for delirium tremens varies with the presence of underlying disease. Higher mortality is associated with superimposed pneumonia, meningitis, pancreatitis, gastrointestinal bleeding, or major trauma [17,20]. For the untreated patient without serious coexisting medical disease, mortality usually is a consequence of severe dehydration or
hyperthermia, or both, precipitating cardiovascular collapse \[20,21\]. Before adequate therapeutic agents were available, a mortality rate of 24% to 35% was cited in the literature \[22\]. This has been steadily decreasing over time, and with the use of benzodiazepines, intensive supportive care, and earlier recognition of withdrawal has approached 0% to 2% in more recent studies \[17,23,24\].

**Diagnostic Evaluation**

The differential diagnosis of ethanol withdrawal includes other causes of a hyperadrenergic state. Most importantly, ethanol-related hypoglycemia needs to be differentiated from withdrawal. Clinically, these two conditions may appear remarkably similar, although only hypoglycemia rapidly improves after intravenous (IV) glucose administration.

Intoxication with sympathomimetic agents such as cocaine or amphetamine shares many features with ethanol withdrawal, including signs and symptoms of adrenergic excess. Overdose of monoamine oxidase inhibitors, phencyclidine, anticholinergic agents, and lithium, as well as neuroleptic malignant syndrome and serotonin syndrome may all demonstrate marked agitation and confusion. For the elderly patient, almost any therapeutic drug may be associated with delirium, with opioids, benzodiazepines, anticholinergics, and antidepressants being of particular concern \[25\]. Withdrawal from other sedative–hypnotics, such as benzodiazepines, barbiturates, GHB, and baclofen, may precipitate a delirium-tremens-like state (see following discussion).

Significant underlying metabolic, traumatic, and infectious disorders should be excluded for the patient with altered mental status associated with ethanol withdrawal. Differentiation may require lumbar puncture, laboratory tests, and computed tomographic scan of the head. These include CNS emergencies, such as intracranial bleeds, meningitis, and encephalitis; metabolic causes, including hypoxia, hypercarbia, sepsis, thiamine deficiency, and sodium and calcium abnormalities; and endocrine disturbances, such as thyroid storm and pheochromocytoma. Distinguishing between delirium tremens and hepatic encephalopathy may be difficult, especially because these conditions often coexist.

**Management**

A successful strategy for treating ethanol withdrawal must address several key goals: alleviation of symptoms, prevention of progression of withdrawal to a more serious stage, avoidance of complications, treatment of coexisting medical problems, and planning for long-term rehabilitation and drug independence \[6\]. Initial management involves securing the airway, breathing, and circulation. The patients with an altered level of consciousness require oxygen and IV administration of at
least 100 mg thiamine and 50 g glucose. The latter two substrates are particularly important, as Wernicke encephalopathy and hypoglycemia may be confused or coexist with ethanol withdrawal. Severely agitated patients may initially require physical restraints to prevent injury and facilitate sedation. Prolonged use of physical restraints without adequate sedation, however, may be detrimental because agitated patients often continue to struggle against their restraints. Such activity perpetuates the risk for hyperthermia, muscle destruction, and resultant myoglobinuric renal failure. One retrospective review of 35 deaths in delirium tremens found that mortality correlated with the use of restraints and hyperthermia [26].

Volume resuscitation, correction of electrolyte abnormalities, and vigilance in the diagnosis and treatment of coexisting medical and surgical disorders are vital for reducing morbidity and mortality of the patient with delirium tremens [6,16].

Achievement of adequate sedation is the cornerstone of successful treatment of ethanol withdrawal [27]. Sedation alleviates the excitatory manifestations of withdrawal, prevents progression to delirium tremens, and prevents common complications of agitation, including trauma, rhabdomyolysis, and hyperthermia. Although many agents have been used over the years, benzodiazepines have proved the most effective [1,6,16,27,28]. Benzodiazepines, unlike the neuroleptics, are cross-tolerant with ethanol and function as a replacement drug for the short-acting ethanol, increasing the affinity of GABA for the GABA_A receptor [6].

Diazepam (Valium), chlordiazepoxide (Librium), and lorazepam (Ativan) are the most commonly used parenteral agents. All three drugs can easily be given intravenously to facilitate rapid sedation and titration of effect. Of these agents, only lorazepam has reliable intramuscular (IM) absorption [6,14]. Diazepam and chlordiazepoxide are long-acting agents with active metabolites that prolong their therapeutic effect, avoiding the need for frequent dosing that is associated with shorter-acting agents. Lorazepam, a shorter-acting agent, has no active metabolite and is better tolerated in the elderly and in patients with hepatic dysfunction, producing less sedation. Prolonged therapy (e.g., >1 month) with high-dose IV lorazepam, however, has also been associated with acute tubular necrosis secondary to the polyethylene glycol used as the lorazepam diluent. Continuous IV infusion of midazolam, a short-acting agent, has also been recommended in the treatment of delirium tremens. However, this approach requires more vigilant monitoring and does not provide the advantages of a long-acting benzodiazepine that is gradually eliminated over several days. Midazolam infusion is also considerably more expensive than therapy with longer-acting agents [27].
The benzodiazepine of choice in the treatment of ethanol withdrawal remains controversial [29]. Currently, the literature does not support the efficacy of one benzodiazepine over another [6,27,28,30]. Although some investigators have suggested that lorazepam may be the preferred agent [31], long-acting benzodiazepines such as diazepam may be more effective in preventing ethanol withdrawal seizures and contributing to smoother withdrawal with less breakthrough or rebound symptoms [32].

Symptom-triggered benzodiazepine treatment for alcohol withdrawal is strongly encouraged [24,33]. The Clinical Institute Withdrawal Assessment for Alcohol (CIWA-A) scale is a reliable, validated scale to assess severity of alcohol withdrawal, so treatment can be appropriately titrated and individualized. It includes subjective parameters such as anxiety, auditory and visual disturbances, headache, and nausea as well as objective parameters such as tremor, sweating, agitation, and clouding of sensorium. A score >18 indicates the patient is considered severe and at risk for complications if not treated. In severely agitated or intubated patients, subjective parameters may be difficult to evaluate, and a tool such as the Richmond Agitation-Sedation Scale may be used instead [6]. The dose of benzodiazepines needed to achieve adequate sedation varies considerably depending on the patient’s tolerance. Although oral therapy may be appropriate in patients with mild withdrawal, those with significant signs of withdrawal require IV treatment. Therapy with an IV benzodiazepine is titrated to the patient’s needs by the use of frequent boluses until withdrawal symptoms subside. Using such a front-loading technique helps avoid undertreatment or excessive sedation. For example, 5 to 20 mg of diazepam can be administered to the patient every 5 minutes until he/she is quietly asleep but can be easily awakened. Initial safe titration of benzodiazepines requires continual reevaluation by an observer at the bedside. In patients with moderate withdrawal symptoms, a study showed that using a symptom-triggered approach, instead of a fixed-schedule approach, resulted in the administration of less total medication and fewer hours of medication (9 hours vs. 68 hours) [34]. A 2003 study in a surgical ICU demonstrated that this symptom-orientated bolus-titrated approach decreases the severity and duration of alcohol withdrawal symptoms, resulting in reduced medication requirements, fewer days of ventilation, lower incidence of pneumonia, and shorter ICU stay [35].

Failure to obtain adequate sedation with standard doses of the chosen agent should not prompt a switch to an alternative benzodiazepine. Some patients require very high doses to achieve sedation; cases of the patients receiving up to 2,000 mg of diazepam during the first 2 days have been
reported [1]. Recent research into GABA receptor physiology suggests that resistance to large doses of benzodiazepines in some patients with alcohol withdrawal may be due to alterations in GABA<sub>A</sub> receptor subunit expression [36]. In two studies of alcoholics, increased levels of GABA<sub>A</sub> receptor α<sub>1</sub> subunit mRNA was noted in the prefrontal cortex with no change in the expression of α<sub>2</sub>, α<sub>3</sub>, or α<sub>4</sub> mRNA. The total concentration of α subunits also appears to be increased. If the patient with severe alcohol withdrawal does not respond to large doses of a benzodiazepine, such as 200 mg of diazepam or 40 mg of lorazepam over 3 to 4 hours, the administration of an alternative agent may be warranted [6]. Cases requiring greater than 40 mg of diazepam in the first hour are often considered resistant alcohol withdrawal. The sequential addition of other agents may be necessary. A barbiturate, which acts on the GABA<sub>A</sub> receptor regardless of its specific α subunit composition, is often the next agent added [15].

Barbiturates, particularly intermediate and long-acting agents such as pentobarbital and phenobarbital, are cross-tolerant sedative–hypnotic agents that can be used in the treatment of ethanol withdrawal, either alone or as an adjunct for resistant alcohol withdrawal [10,15]. Dosing of phenobarbital may require up to 1,500 to 2,000 mg orally or intravenously on Day 1 in patients with delirium [1]. Although excess sedation and a greater tendency to produce respiratory depression may be more of a concern with barbiturates as compared with benzodiazepines, the drugs are still titrated until the patient is quietly asleep but easily awakened [6,37]. Withdrawal patients with idiopathic or post-traumatic epilepsy who require maintenance anticonvulsant levels may particularly benefit from this alternative strategy.

Recent research also suggests that changes in NMDA glutamate receptor physiology may be important in both clinical signs and symptoms of ethanol withdrawal and the excitotoxic neuronal cell death that may occur. In animal studies, NMDA receptor antagonists may attenuate the development of ethanol dependence if administered concomitantly, and may prevent withdrawal seizures and neuronal excitotoxicity if given during periods of withdrawal [12]. The patients who are refractory to high dose GABA<sub>A</sub> agonists may potentially benefit from addressing the glutaminergic as well as the GABA-ergic manifestations of ethanol withdrawal.

Options in the setting of refractory ethanol withdrawal are limited, but drugs such as propofol, which possess both GABA agonist and NMDA antagonist properties, may be particularly helpful. Although it maintains cross-tolerance with GABA receptors, the effect is less than benzodiazepines and does not preclude the use of benzodiazepines [38]. Propofol, a sedative–hypnotic agent used for induction and maintenance
of anesthesia, has been used successfully for treatment of severe ethanol withdrawal that is resistant to large doses of benzodiazepines (>1,000 mg per day) [6,38,39]. Like ethanol, it acts as an agonist at the GABA<sub>A</sub> receptor and also inhibits the NMDA receptor. Its onset of action is rapid, it is easily titratable, and sedative effects wear off quickly after short-term use (<72 hours). The fact that it addresses the glutaminergic as well as the GABA-ergic aspects of ethanol withdrawal may be one reason for its increased apparent effectiveness in patients resistant to standard therapy with benzodiazepines. Disadvantages of its use include prolonged sedation and the potential for propofol infusion syndrome when it is used for extended periods [39]. A recent retrospective cohort of the patients treated with benzodiazepine monotherapy compared to those with added propofol demonstrated similar length of alcohol withdrawal, length of stays, and mechanical ventilation with fewer benzodiazepine boluses in the propofol group [40]. Another retrospective study suggested longer and more complicated hospital stays in those receiving propofol as part of their regimen [41].

Ketamine is another agent with NMDA antagonistic properties that has been used for the treatment of alcohol withdrawal. Unlike propofol, it has no GABA effects. One retrospective review has demonstrated a reduction in benzodiazepine requirements, but additional data are still required before ketamine can be recommended [42].

Since 2008, reports of successful use of dexmedetomidine, an α<sub>2</sub>-receptor agonist, have been emerging [43]. This agent was designed from clonidine to maximize sedation. It has anesthetic, anxiolytic, analgesic, and sympatholytic effects and is indicated for sedation, but does not cause significant respiratory depression [44]. Recent studies have shown its use can decrease the amount of benzodiazepine used in the first 24 hours, though may not reduce long-term benzodiazepine use in alcohol withdrawal [45]. When compared with propofol, it seems to produce less hypotension, lower intubation rates, decreased ICU length of stays, and comparable benzodiazepine use [46]. Bradycardia may occur more frequently. Because dexmedetomidine has no GABA agonistic properties, its use does not obviate the need for benzodiazepines but may be beneficial in controlling the hyperadrenergic picture that occurs during withdrawal.

Other central adrenergic agonists, such as the α<sub>2</sub>-receptor agonists clonidine and lofexidine, have been promoted as primary agents and adjuncts to sedative–hypnotic treatment in the treatment of alcohol
withdrawal. Clonidine acts centrally to attenuate sympathetic outflow from the locus ceruleus [14]. Although α₂ agonists may help relieve mild withdrawal symptoms such as tremor, diaphoresis, and tachycardia, there is no evidence that they prevent delirium tremens [6]. A double-blind study comparing oral benzodiazepines (diazepam or alprazolam) to clonidine in the treatment of mild ethanol withdrawal showed that the benzodiazepines were significantly more efficacious in decreasing withdrawal symptoms [47]. β-Blockers have also been used as agents in the treatment of ethanol withdrawal. These agents do not prevent agitation, hallucinations, confusion, and seizures and should be used only as adjunctive treatment [6].

IV and oral ethanol have been used to suppress withdrawal and continue to be used by some medical practitioners, especially surgeons [48]. However, IV ethanol intensifies the biochemical abnormalities associated with ethanol metabolism, shifting energy production toward lactate and ketogenesis [49]. The use of ethanol in the treatment of ethanol withdrawal is not recommended [50].

Baclofen is a GABA<sub>B</sub> agonist that appears to have a role in the treatment of alcohol withdrawal. In a randomized, controlled trial, it was comparable to benzodiazepines in relieving symptoms of moderate alcohol withdrawal in an outpatient setting [51]. It has also been shown to be more effective than placebo in controlling craving and in inducing abstinence from alcohol [52]. The mechanism for this effect may be due to the influence of GABA<sub>B</sub> agonist on the mesolimbic dopamine pathway.

Baclofen has not been studied for use in the treatment of alcohol withdrawal in the intensive care setting and a recent COCHRANE review suggested additional data were needed to draw conclusions about its role in alcohol withdrawal [53].

Sodium oxybate, the sodium salt of γ-hydroxybutyric acid (GHB), is another GABA<sub>B</sub> agonist which recent research has suggested may have a role in the treatment of alcohol withdrawal. It is currently approved for use in some European countries. In randomized, controlled trials, it was comparable to benzodiazepines and clomethiazole in relieving symptoms of moderate alcohol withdrawal in an outpatient setting. Transient vertigo was the most commonly reported side effect, but also occurred with clomethiazole and benzodiazepine treatment. GHB may resolve withdrawal-associated symptoms of anxiety, agitation, and depression more quickly than benzodiazepines, possibly due to its action on dopaminergic and serotonergic neurotransmitter systems. This method of treatment is not commonly used, and further study is warranted.

The use of phenothiazines and butyrophenones to treat ethanol withdrawal has been associated with excessive fatalities [27,49]. These agents have been shown to lower the seizure threshold, induce
hypotension, impair thermoregulation, prolong the QT interval, and precipitate dystonic reactions [6]. These drugs have no role in the management of sedative–hypnotic withdrawal.

Magnesium sulfate has been suggested as a potential therapy for alcohol withdrawal, but studies have been concerning for biases and limited in scope. Currently, too little data are available to confirm that magnesium supplementation helps alleviate signs or symptoms of alcohol withdrawal, either in normomagnesemic or in hypomagnesemic patients [54].

Valproate has been suggested as an alternative or adjunctive treatment for ethanol withdrawal. It appears to potentiate GABA-ergic neural transmission through a variety of mechanisms, including activation of glutamic acid decarboxylase. Although there is evidence that valproate may be effective in alleviating withdrawal symptoms, further research is needed before it can be recommended for use in ethanol withdrawal [55].

Adequate sedation of the patient with early signs of withdrawal prevents the development of ethanol withdrawal seizures and progression to delirium tremens. The patients who have had an ethanol withdrawal seizure are at risk for progression to delirium tremens and should be sedated with benzodiazepines or barbiturates, as previously discussed. A randomized, controlled trial evaluating patients presenting to the emergency department with ethanol withdrawal seizures and lacking other signs of moderate alcohol withdrawal showed that a one-time dose of lorazepam, 2 mg IV, was more effective than placebo in preventing recurrent ethanol withdrawal seizures [56]. No evidence has been shown to prove that phenytoin is efficacious in the treatment or prevention of ethanol withdrawal seizures [6,57]. Clinical studies failed to show any significant benefit of IV phenytoin when compared with placebo in the prevention of subsequent ethanol withdrawal seizures [57].

The use of anticonvulsants to prevent or treat ethanol withdrawal seizures should be limited to the patients with an underlying seizure disorder who require maintenance anticonvulsant therapy [6]. These patients often seize at the onset of mild withdrawal secondary to poor compliance with their anticonvulsant regimen and require restoration of adequate serum levels with an anticonvulsant such as phenytoin. The patients who present with an apparent ethanol withdrawal seizure but do not have a history of either underlying seizure disorder or previous ethanol withdrawal seizures require a full seizure workup. For those rare patients in ethanol withdrawal in whom status epilepticus develops, aggressive anticonvulsant treatment is indicated with phenobarbital in addition to benzodiazepines. Because status epilepticus and seizures during delirium tremens are rare sequela of ethanol withdrawal, their occurrence requires a search for underlying traumatic injuries and infection, regardless of any previous history of ethanol withdrawal
seizures.

Adequate early treatment with benzodiazepines usually suppresses significant manifestations of withdrawal and prevents progression to delirium tremens. If delirium tremens is already manifest, sedation with a benzodiazepine does not completely reverse mental status abnormalities. This may be a consequence of the incomplete cross-tolerance of benzodiazepine with ethanol or perhaps the lack of immediate reversibility of some of the CNS effects of withdrawal.
BENZODIAZEPINE WITHDRAWAL

Since their introduction in the early 1960s, benzodiazepines have replaced the barbiturates as the most widely prescribed sedative–hypnotic agents. Initially, these newer agents were not thought to have the same serious withdrawal problems associated with the barbiturates [58]. Subsequent experience has shown that withdrawal from benzodiazepines may be as severe as withdrawal from barbiturates or ethanol. It is estimated that 5% to 10% of the adults in the United States use benzodiazepines on a regular basis [59]. The early signs of withdrawal from benzodiazepines are the same as those of ethanol withdrawal. Differences include delayed time of onset, depending on the duration of action of the agent involved, and the presence or absence of active metabolites. When delayed tachycardia, hypertension, and irritability develop in a hospitalized patient, prior benzodiazepine abuse should be suspected.

Pathophysiology

Signs and symptoms of benzodiazepine withdrawal occur when tolerant patients experience a decline in brain benzodiazepine levels. Individuals who have not developed tolerance do not experience symptoms of withdrawal. The patients who have taken therapeutic amounts of these drugs over an extended period may experience withdrawal (therapeutic dose withdrawal) [58], although more commonly it occurs in those who have been regularly taking higher than recommended antianxiety doses [60]. A high daily dose and long duration of benzodiazepine use correlate with a greater risk of developing a moderate-to-severe withdrawal syndrome [61]. Although withdrawal usually occurs after abrupt discontinuation of these medications, it may occur to a lesser extent during drug tapering [62]. Iatrogenic benzodiazepine withdrawal has also been described for the patients following discontinuation of midazolam-induced sedation in the ICU [63].

The mechanisms for benzodiazepine tolerance and withdrawal involve modulation of GABA_A receptor conformations and subunits, similar to those that occur with chronic ethanol use, may be responsible [64]. Ultimately, a decrease in the availability of exogenous benzodiazepine results in unopposed nervous system stimulation and an increase in
agitation and anxiety.

Variability in the time course and severity of withdrawal among the various benzodiazepines can be explained by their differing pharmacokinetics [58]. Drug half-life and the presence of active metabolites correlate with the onset, frequency, and severity of withdrawal symptoms. The onset of withdrawal from shorter-acting agents without active metabolites, such as lorazepam or alprazolam, may be precipitous, with marked symptoms as early as 24 hours after cessation of the drug. Signs of withdrawal from longer-acting agents, such as diazepam, which have a long elimination half-life in addition to active metabolites, may be delayed for 8 days or longer. Withdrawal symptoms from long-acting benzodiazepines may persist for months [58]. Concurrent use of other cross-tolerant sedative–hypnotic substances, such as ethanol, barbiturates, chloral hydrate, glutethimide, ethchlorvynol, or meprobamate, along with benzodiazepines increases the probability of developing withdrawal on abrupt discontinuation of these substances.

The administration of the competitive benzodiazepine antagonist flumazenil can result in iatrogenic benzodiazepine withdrawal. Flumazenil is sometimes used to reverse sedation in the settings of benzodiazepine overdose, IV conscious sedation, and general anesthesia. However, it may not fully reverse respiratory depression associated with benzodiazepine toxicity [60]. A history of benzodiazepine use and dependence may not be available when unconscious patients are admitted to the ICU, and benzodiazepine withdrawal with seizures and death has been reported after the use of flumazenil. Recently, safety was reported in a very small study of flumazenil use in the emergency department [65]. Flumazenil should be used with caution (see Chapters 123 and 125).

**Clinical Manifestations**

Benzodiazepine withdrawal is characterized by CNS excitation and autonomic hyperactivity. Mild early manifestations of withdrawal include psychological symptoms such as anxiety, apprehension, irritability, mood swings, dysphoria, and insomnia. Somatic complaints commonly include nausea, palpitations, tremor, diaphoresis, and muscle twitching.

More severe signs of withdrawal include vomiting, cramps, tachycardia, postural hypotension, and hyperthermia. Significant neuromuscular hyperactivity may be manifested as fasciculations, myoclonic jerks, and seizures [16,58]. Agitated delirium accompanied by hallucinations and paranoid delusions, and catatonia, have been described [66].

For the patients taking clonazepam, withdrawal symptoms may
develop 3 to 4 days after cessation of therapy. Clonazepam withdrawal may be precipitated or accentuated, or both, by concomitant neuroleptic therapy [67].

**Diagnostic Evaluation**

Benzodiazepine withdrawal may be difficult to distinguish from an underlying anxiety disorder [58,60]. The time course of the symptoms helps distinguish these two diagnoses. Withdrawal symptoms often worsen rapidly in the early period, followed by gradual improvement and resolution. Unmasked anxiety disorders tend not to deteriorate significantly and persist with time. Perceptual disturbances, not generally associated with underlying anxiety disorders, are commonly found during early withdrawal and may also help distinguish withdrawal from the return of anxiety. These disturbances include paresthesias, tinnitus, visual abnormalities, vertigo, metallic taste, depersonalization, and derealization [16,58].

**Management**

Treatment strategies for benzodiazepine withdrawal are similar to those used for ethanol withdrawal with the exception that reintroduction of the drug is often warranted for benzodiazepine withdrawal. Reinstitution of the drug at a dose that relieves withdrawal symptoms followed by slow withdrawal during 2 to 4 weeks minimizes symptoms and affects the desired decrease in CNS tolerance. Alternatively, a similar cross-tolerant agent can be used. A long-acting benzodiazepine such as diazepam or chloridiazepoxide is preferred in severe withdrawal. Short-acting agents may be disadvantageous because maintenance of therapeutic serum drug levels requires frequent drug administration. In patients with moderate-to-severe symptoms (e.g., seizures and delirium), small IV boluses, such as 5 mg of diazepam, should be given until adequate sedation is achieved. The patients experiencing milder symptoms can be treated by the oral route. Barbiturates such as pentobarbital and phenobarbital can also be used in the treatment of benzodiazepine withdrawal [60].

β-Blockers and clonidine have also been used for the treatment of benzodiazepine withdrawal. Propranolol (10 to 40 mg every 6 hours) may help ameliorate tremor, muscle twitching, tachycardia, and hypertension. However, it has little effect on anxiety, agitation, and dysphoria. Clonidine use has also been advocated, although its efficacy in modulating the intensity, severity, and duration of withdrawal has been questioned. As with ethanol withdrawal, it is important to realize that treating peripheral manifestations of withdrawal may obscure early signs of impending delirium and impedes the assessment of adequate sedation. Phenothiazines and butyrophenones exhibit no cross-tolerance to the
benzodiazepines and do not have a role in the treatment of benzodiazepine withdrawal, for the same reasons seen in ethanol withdrawal.

Limited data are available on the treatment of flumazenil-induced benzodiazepine withdrawal. Because flumazenil has a relatively short half-life (approximately 1 hour), supportive care should be sufficient in the treatment of mild withdrawal symptoms. The precipitation of seizure activity may require treatment with a benzodiazepine or barbiturate. Owing to flumazenil blockade of benzodiazepine binding site, higher doses of GABA-ergic agonists may be required [58,60].
**γ-HYDROXYBUTYRATE WITHDRAWAL**

Withdrawal from the commonly abused street drugs GHB or its congeners γ-butyrolactone and 1,4-butanediol (see Chapter 121) may be dramatic and potentially life-threatening [68]. The pathophysiology is similar to that for benzodiazepine withdrawal. Heavy users of these chemicals report using multiple daily doses (as frequent as every 1 to 3 hours) around the clock [69]. GHB acts as an agonist at GHB and GABA\(_B\) receptors. Withdrawal symptoms may include agitation, mental status changes, hypertension, and tachycardia. Other findings are tremulousness, diaphoresis, tachypnea, rigidity, irritability, paranoia, insomnia, and auditory and visual hallucinations [68]. High-frequency users appear to be at greatest risk for developing withdrawal delirium after abrupt discontinuation of these agents. Onset of symptoms may begin as early as 1 to 6 hours after the last dose [70]. Severe withdrawal symptoms may persist from 5 to 15 days onward and require prolonged ICU care. Many of these patients require physical restraints and heavy sedation. The use of IV benzodiazepine and other cross-tolerant agents is recommended in the management of these patients, although some patients may be refractory to large doses of benzodiazepines. Successful treatment of this subset of the patients with propofol, barbiturates and baclofen have been reported, but rigorous prospective clinical trials have yet to be conducted [68]. Barbiturates such as pentobarbital may be helpful because unlike benzodiazepines, they are capable of opening GABA\(_A\) chloride channels independently of GABA’s presence.

Pentobarbital dosages used in case series were 1 to 2 mg per kg IV every 30 to 60 minutes, titrated to improvement in vital signs and altered sensorium [71]. Baclofen’s usefulness may stem from the fact that like GHB, it is an agonist at GABA\(_B\) receptors, whereas benzodiazepines act only on the GABA\(_A\) receptor. One case report describes dosing of 10 mg orally three times daily successfully prevented seizures which occurred every time GHB was withdrawn from a dependent patient [72].
BACLOFEN WITHDRAWAL

Baclofen is a GABA_B receptor agonist used to treat spasticity resulting from multiple sclerosis or CNS injury. It can be taken orally or delivered by an intrathecal pump, which allows higher CNS levels without the side effects associated with large oral doses. An abrupt discontinuation or decrease in either oral or intrathecal baclofen dose may result in a withdrawal syndrome [73]. The pathophysiology is similar to that for benzodiazepine withdrawal. There are many scenarios in which an intrathecal drug delivery system may fail, including errors in programming the pump or filling the reservoir, the development of kinks or occlusions in the tubing, and battery failure.

Onset of withdrawal symptoms may occur within a few hours to a few days after a decrease in baclofen dose or sudden intrathecal pump failure [74,75]. Mild-to-moderate withdrawal symptoms may include increased spasticity, tachycardia, hypertension, fever, neuromuscular rigidity, hyperreflexia, psychosis, and delirium. Severe withdrawal may result in coma, seizures, rhabdomyolysis, hyperthermia, disseminated intravascular coagulation, circulatory failure, delirium, and coma. The features of withdrawal from oral and intrathecal baclofen are similar with onset at similar times following last administration, though some reports indicate hallucinations may be more frequent in those withdrawing from oral baclofen. The mechanism for this is not entirely known. Occasionally, the patients may develop a reversible cardiomyopathy. In the most severe cases, multiorgan failure and death may occur [73,76]. The delirium observed with baclofen withdrawal may resemble the altered mental status caused by baclofen intoxication, and baclofen intoxication should always be considered along with withdrawal in the differential diagnosis of delirium in the patient on baclofen. The severe withdrawal syndrome may also mimic other conditions such as infection, serotonin syndrome, and neuroleptic malignant syndrome. In cases such as these, the diagnosis may be easy to miss, and evaluation for pump failure should always be considered. Any reason for pump failure should be identified and remedied, with the previous intrathecal baclofen dose reinstituted [77]. Pump integrity and function may be assessed by plain films, dye studies, nuclear medicine flow studies, port aspirations, or if necessary, operative exploration. Cautiously administering a bolus of baclofen by the pump, by way of lumbar puncture, or by a lumbar drain, and assessing for improvement in 30 to 60 minutes may help confirm the diagnosis. Oral baclofen may also be used, though large doses may be needed and clinical improvement may be delayed by several hours [78].

In addition to supportive care, the most important step in the
management of baclofen withdrawal is the replacement of the baclofen. The patients who were receiving oral therapy may have the drug administered by nasogastric tube if they are unable to take it by mouth secondary to their withdrawal symptoms. The patients withdrawing from intrathecal baclofen may require high doses of oral baclofen, or may not respond to oral replacement therapy [77]. Replacement oral baclofen doses for intrathecal baclofen withdrawal often range between 10 and 30 mg orally, every 4 to 8 hours [78]. If there is any delay in administering baclofen intrathecally in these patients, other sedative medications such as benzodiazepines, barbiturates, or propofol should be provided intravenously. As with oral baclofen dosing and with benzodiazepine treatment of severe ethanol withdrawal, large doses of these agents may be necessary to control severe symptoms, with attention to airway support if the patient is not already intubated. Cyproheptadine (4 to 8 mg orally every 6 to 8 hours) has been suggested as a useful adjunctive therapy in patients with intrathecal baclofen withdrawal who are well enough to take oral medications. More study is needed before this can be definitively recommended.
OPIOID WITHDRAWAL

Opioid withdrawal occurs when a tolerant individual experiences a decline in CNS levels of a chronically used opioid. Unlike withdrawal from sedative–hypnotic agents, the manifestations of opioid withdrawal are not usually life-threatening [16]. Recognition of the problem facilitates optimal management of the critically ill patient.

Pathophysiology

Opioid receptors in the locus ceruleus bind exogenous opioids, such as heroin, methadone, or codeine, as well as endogenous opioid-like substances known as endorphins and enkephalins. Stimulation of opioid receptors reduces the firing rate of locus ceruleus noradrenergic neurons, resulting in the inhibition of catecholamine release. The stimulation of inhibitory adrenergic receptors, also found in the locus ceruleus, causes a similar reduction in sympathetic outflow. Chronic opioid use may produce an increase or upregulation of these adrenergic receptors. Subsequent withdrawal of opioids results in increased sympathetic discharge and noradrenergic hyperactivity.

The time course of the withdrawal syndrome depends on pharmacokinetic parameters of the individual opioids. Withdrawal symptoms usually appear about the time of the next expected dose [16,79]. Withdrawal from heroin, which has a short half-life, begins 4 to 8 hours after the last dose, whereas withdrawal from methadone, with a long half-life, is delayed until 36 to 72 hours after the last dose. Withdrawal symptoms are more intense if the opioid has a shorter half-life, whereas symptoms are less dramatic but often more prolonged if the abused opioid has a longer half-life. Methadone withdrawal may not peak until the 6th day of abstinence and may persist for weeks. Because prolonged opioid use may be required to facilitate ventilator management in intensive care patients, iatrogenic opioid withdrawal may complicate ventilator weaning [80].

Clinical Manifestations

Early signs of opioid withdrawal include mydriasis, lacrimation, rhinorrhea, diaphoresis, yawning, piloerection, anxiety, and restlessness [16,79]. With time, these symptoms may worsen and be accompanied by mild elevation in pulse, blood pressure, and respiratory rate. Myalgias, vomiting, diarrhea, anorexia, abdominal pain, and dehydration accompany more severe withdrawal. Although these patients may
become extremely restless, fever and central agitation such as seizures (except in cases of neonatal withdrawal) and mental status alteration are not part of opioid withdrawal. An intense craving for the drug accompanies withdrawal. Recognition of these signs and symptoms in the ICU patient obviates the need for extensive evaluation of the gastrointestinal symptoms and puts clinically puzzling pain complaints in perspective. Appropriate therapy alleviates the patient’s discomfort and facilitates the management of more pressing ICU problems. After the resolution of most of the objective signs of withdrawal, subjective symptoms, especially dysphoria, may persist for weeks.

Opioid withdrawal may occur suddenly in the opioid-dependent patient given naloxone [81]. This iatrogenic withdrawal often occurs after naloxone is given to the patient who is lethargic or comatose and has unrecognized opioid dependency. Naloxone-induced withdrawal may also occur in dependent patients after use of naloxone to reverse the effects of an opioid used during procedural sedation. Vomiting and subsequent aspiration of the unconscious patient are the major complications arising from this problem, an important concern in the setting of mixed sedative intoxications. This abstinence syndrome is of brief duration due to the short half-life of naloxone, lasting 20 to 60 minutes, and treatment with opioids to reverse the unwarranted effects of naloxone is not indicated. Naloxone, if required, should not be withheld in the dependent patient. A starting dose of 0.04 to 0.10 mg should be used and titrated until the desired effect is achieved or mild signs of withdrawal occur. Coma or hypoventilation that persists after the onset of withdrawal signs is not reversed by the administration of additional naloxone. This suggests another contributing substance or cause for coma [82].

Naltrexone, an orally active opioid antagonist, induces withdrawal symptoms for up to 48 hours. Nalmefene, another opioid antagonist, may also cause prolonged withdrawal symptoms in the opioid-tolerant patient. A less commonly recognized cause of opioid withdrawal is the use of agonist–antagonist in the opioid-dependent person. Drugs with agonist–antagonist activity include pentazocine (Talwin), nalbuphine (Nubain), butorphanol (Stadol), and buprenorphine (Subutex).

Management

Treatment of opioid withdrawal is a two-tier approach, using cross-tolerant opioid replacement or sympatholytic therapy (e.g., clonidine), or both. The benzodiazepines are not cross-tolerant with opioids. Their role
is limited to the management of significant anxiety associated with opioid withdrawal.

Substitution of long-acting methadone for heroin has played a prominent role in the management of opioid addiction. First used in the 1960s for the treatment of heroin addiction, methadone was chosen for its chemical similarity to heroin, oral availability, and long half-life (24 to 36 hours). Although the use of methadone for the outpatient treatment of opioid dependence is tightly regulated, physicians do not need special licensing to prescribe methadone to hospitalized patients. Methadone administered by nasogastric tube or subcutaneously has been successfully used to treat iatrogenic opioid withdrawal symptoms as well. The use of methadone may shorten the phase of ventilator weaning in these patients [83].

Methadone may be useful for treating the uncomfortable symptoms in patients who depend on any opioid. The dose should be judiciously titrated to relieve symptoms but avoid oversedation. A safe initial dose is 20 mg orally or 10 mg IM. The IM route guarantees absorption in the vomiting patient [79]. Relief of symptoms usually occurs within 30 to 60 minutes when the drug is given parenterally and longer when it is given orally. A second 10 mg IM dose can be given if significant relief is not achieved 1 hour after the first IM dose. Administering 10 to 20 mg by IM route blocks most manifestations of physiologic withdrawal, although some patients may require 20 to 40 mg daily or divided twice per day to avoid psychological withdrawal. In general, dosing to prevent withdrawal symptoms requires considerably less drug than dosing for methadone maintenance. Although withdrawal from opioids should not be attempted during an acute medical illness, once they are medically stabilized, heroin-dependent patients can be tapered with methadone over 1 week [84].

Methadone-dependent patients require 4 weeks or more of gradually decreasing dosages [84]. Notable drugs that interact with methadone, lowering its plasma concentration and potentially precipitating opioid withdrawal, include rifampin and phenytoin.

For those patients enrolled in methadone maintenance programs, considerably larger doses of methadone are often employed. Some of these patients, particularly early in treatment, may continue to abuse heroin. Higher methadone doses, as much as 150 mg a day or more, have been recommended as a means to reduce concurrent heroin use and retain patients in treatment programs [85]. Some community clinics use doses as high as 200 to over 300 mg per day in selected patients.

The treatment of pain in patients receiving methadone may require the use of additional opioid analgesia, such as morphine, codeine, or oxycodone. In patients on methadone maintenance, the established maintenance dose may not provide adequate analgesia because of
tolerance to the analgesic effects of methadone. Successful pain relief requires the continuation of the methadone maintenance dose supplemented by additional analgesics [86].

Every attempt should be made to minimize significant withdrawal manifestations for the opioid-dependent pregnant patient. Withdrawal in these patients may adversely affect the developing fetus, causing fetal distress and even intrauterine death. Oral methadone maintenance is more compatible with maternal and fetal well-being than continued heroin abuse and would likely also decrease the risk of intrauterine acquisition of acquired immunodeficiency syndrome [87]. Cautious treatment of these patients with sufficient methadone to avoid withdrawal may avert these additional complications. After delivery, the neonate must be hospitalized and withdrawn from the drug. In selected pregnancies, lowering the maternal methadone dosage may lead to decreased incidence and severity of neonatal withdrawal [88].

Although methadone has been extensively used for decades to help opiate addicted patients circumvent the health problems associated with illicit IV drug abuse, there are valid concerns about its safety as well. Methadone is known to cause dose-related respiratory depression and sleep apnea, which varies greatly based on an individual patient’s underlying tolerance. The risk of apnea increases when methadone is combined with other depressant drugs [89]. Other concerns have increasingly come to light in recent years. Disproportionate numbers of the patients on methadone were found to have suffered sudden cardiac death, often without underlying structural heart disease [89]. Though the majority of methadone associated sudden deaths are likely due to respiratory depression, it was also discovered that methadone is a potent potassium channel blocker, especially at higher doses. This prolongs cardiac repolarization (lengthening the QTc interval and predisposing to Torsades de Pointe). Although it is unknown how clinically significant this finding may be, some experts suggest that QTc intervals be checked prior to initiating methadone therapy and be followed during chronic therapy to watch for lengthening of the QTc [90].

In recent years, buprenorphine, a partial mu-opioid agonist and K-opioid antagonist, has been increasingly advocated as an alternative to methadone for both maintenance, short-term management of opioid detoxification and opioid withdrawal during concurrent medical illness [91,92]. Buprenorphine can be given orally, sublingually, intramuscularly, or intravenously. Because of its partial agonist activity, it causes less CNS and respiratory depression and has a ceiling effect, so is less likely to be dangerous in overdose than methadone (though respiratory depression may still occasionally be seen, especially at higher doses, and deaths have been reported). This characteristic also renders it able to block the euphoric effects of heroin and morphine. It produces
only a mild withdrawal syndrome when treatment is ceased, but care should be taken when initiating therapy in opioid-dependent patients as it may precipitate withdrawal. Of interest, one case of deliberate buprenorphine overdose resulted not in respiratory depression but severe opioid withdrawal lasting 4 days [93]. Opioid withdrawal symptoms may resolve more quickly with buprenorphine than with methadone but the effectiveness for maintenance treatment of heroin dependence is similar between the two agents [94]. Buprenorphine does not seem to have the same propensity to prolong the QT interval as methadone [90]. Buprenorphine has an even longer half-life than methadone of approximately 40 hours, so an additional benefit is that it may be administered every other day or even three times a week as maintenance therapy for opioid addicted patients. Special training and licensing are required for physicians who wish to prescribe buprenorphine or methadone (when used as treatment for opioid dependence) on an outpatient basis.

Sublingual buprenorphine tablets and solution are available as monotherapies as well as in combination with naloxone in a 4:1 (buprenorphine:naloxone) ratio (Suboxone). The naloxone is poorly absorbed sublingually and therefore does not interfere with buprenorphine’s effects when taken as directed. Naloxone is added to the buprenorphine to block buprenorphine’s euphorogenic effects if an attempt is made to divert the drug for illicit IV use (crushing and dissolving tablets, among others).

Sublingual dosing of buprenorphine for opioid dependence maintenance therapy starts with an introductory dose of 4 to 8 mg, based on the patient’s degree of neuroadaptation to opioids. Current recommendations are for the use of buprenorphine–naloxone therapy (Suboxone). Dosing may be advanced by 4 mg per day on subsequent induction days as necessary to control withdrawal symptoms up to a total dose of 32 mg per day. Symptomatic management should be undertaken for additional withdrawal symptoms. Because buprenorphine binds more tightly to the mu-opioid receptor than does heroin or methadone, it displaces any residual drug from the receptor and blocks its agonist effects since buprenorphine itself is only a partial agonist. Ideally buprenorphine induction is done when the patient is exhibiting early signs of withdrawal, such as yawning and rhinorrhea, which lowers the chance of precipitating further withdrawal as buprenorphine will not be displacing a more potent opioid. This is usually at least 6 hours after the last heroin use. If the patient is on methadone, the dose of methadone
should be tapered to no more than 30 mg per day for at least 1 week prior to transitioning medications. This minimizes risk of withdrawal and improves success; starting on too high a dose increases the risk of precipitated withdrawal. The first dose of buprenorphine should be given at least 24 hours after the last dose of methadone. In this instance, Suboxone monotherapy is preferred with transition to combined therapy with naloxone on Day 2. Precipitated withdrawal symptoms usually start 1 to 4 hours after the buprenorphine dose and last about 12 hours. These symptoms are worst during the first day, but the patients transitioning to buprenorphine from methadone may experience mild discomfort and dysphoria for up to 1 to 2 weeks, depending on how much methadone they were using previously. Symptomatic treatment with medication such as clonidine may be employed during this period as needed.

In addition to maintenance therapy, various tapering opioid detoxification regimens using buprenorphine exist, with starting doses ranging from 1 to 8 mg daily. Therapy may be tapered over 5 to 14 days [95].

Clonidine, a central α₂-adrenergic agonist that binds to the α₂-receptors in the locus ceruleus, is also used to treat opioid withdrawal [96]. Stimulation of central α₂-receptors results in feedback inhibition of the norepinephrine activity, decreasing the firing rate of the noradrenergic neurons. These noradrenergic neurons also possess opioid receptors whose stimulation produces a similar reduction in sympathetic activity through the same intracellular messenger system. Clonidine used without the addition of a replacement opioid has been found to be as effective as methadone in preventing opioid withdrawal symptoms in medically ill hospitalized patients. Clonidine may be administered in doses of 0.1 to 0.2 mg every 4 to 6 hours. Treatment is often continued for 5 to 10 days and then slowly tapered by 0.2 mg per day. Clonidine transdermal patches provide steady-state clonidine levels and may also be useful. Tachyphylaxis to the effects of clonidine may develop by 10 to 14 days. The most concerning side effect of clonidine is hypotension, especially with the first dose. This requires close monitoring. In more recent studies, the patients administered buprenorphine–naloxone were more likely to complete short-term detoxification programs and report fewer withdrawal and craving symptoms than those treated with clonidine [97]. Although buprenorphine–naloxone seems to be more efficient than clonidine in reducing opioid withdrawal symptoms during the initial course of detoxification differences may wane after a few days [98]. The long-term success of this approach is unclear.

Combination therapy with clonidine and naltrexone has also been used for rapid opioid detoxification. Proponents of this approach emphasize the shortened period of withdrawal associated with the addition of naltrexone. Continuing naltrexone as deterrent therapy after opioid
withdrawal (akin to the use of disulfiram with alcoholics) has also been advocated, but this approach has a high attrition rate. Delirium has been reported during rapid opioid detoxification of methadone maintenance patients.

Administering high doses of opioid antagonists to addicted individuals while under anesthesia has been suggested as a method of achieving detoxification from opiates within 24 to 48 hours. This method, known as ultrarapid detoxification, has been associated with pulmonary and renal failure as well as other complications, including death. Additionally, long-term follow-up has demonstrated relapse of drug abuse in many of these patients [99]. This approach is not recommended.
NICOTINE WITHDRAWAL

In the United States, 18% of the population continues to smoke tobacco cigarettes [100]. Tobacco exposure is a major risk factor for multiple respiratory, cardiovascular and infectious diseases, as well as carcinogenic. Nicotine binds nicotinic acetylcholine receptors and induces their upregulation. Nicotine withdrawal has been identified as a risk factor for agitation and delirium in the ICU [101]. Cessation of smoking has been associated with sweating, drowsiness and bradycardia [16]. Symptoms generally begin 1 to 2 days after last use, peak within the first week, and persist for 2 to 4 weeks or longer with cravings lasting up to 6 weeks [101]. Supportive care is often used. Nicotine replacement can be used to prevent withdrawal or alleviate symptoms with transdermal nicotine patches to reduce symptoms. Gums and lozenges containing nicotine are also available but their use is often limited in the ICU. Recent studies have evaluated mortality in association with nicotine replacement but are limited by their small size. The only prospective evaluation demonstrated no difference in mortality, length of stay or ventilator use in smokers receiving nicotine replacement versus those not receiving replacement therapy [102]. Additional evidence is necessary before a formal conclusion can be made. Bupropion, a long-acting serotonin and norepinephrine reuptake inhibitor, may be used at low doses alone or in combination with nicotine replacement to assist with smoking cessation. Varenicline is a α4β2 nicotinic receptor partial agonist that has also been used for smoking cessation. Clinical studies regarding the roles of bupropion and varenicline for critically ill adults are lacking [101].

HOSPITAL AND COMMUNITY DISASTER RESPONSE

The Importance of Hospitals for Disaster Response

Disasters are, by definition, unplanned occurrences. Large-scale catastrophes can strike communities and their hospitals without warning, with events ranging from sudden traumatic events, such as an earthquake or explosion, to sustained pandemics such as H1N1 influenza or the severe acute respiratory syndrome (SARS). Hospitals are a major source of a community’s medical care, particularly during acute emergencies. In the setting of a large-scale disaster, ambulances will routinely transport critically ill or injured patients to the nearest hospital, often independently of a given hospital’s stated capabilities. It is especially difficult to provide critical care outside of the hospital setting during such a disaster. Although it may be possible to provide medical care in a building of opportunity, such as a school gymnasium, for low-acuity patients, the provision of critical care in such a setting requires significant amounts of medical equipment, supplies, and trained staff.

In order to maintain its capability to care for the most critically ill patients during a disaster, the hospital must be part of a community-based health care response system that can be efficiently mobilized during a catastrophic event. Hospitals which are accredited by the Joint Commission or other accrediting agencies must meet specific requirements for disaster preparedness. These requirements include
continuity-of-operations plans, an internal operations center with an incident command structure, and the planning and conduct of disaster response exercises in coordination with the neighboring community [1].

The Centers for Medicare and Medicaid Services (CMS) published updated emergency preparedness requirements for both health care providers and suppliers on September 16, 2016. The primary goal of the updated CMS regulations is to maintain access to health care services during emergencies. Requirements are broken down into four elements: (1) emergency planning, (2) policies and procedures, (3) communication, and (4) training and testing. In order to continue to receive CMS funding, hospitals have until November 15, 2017 to comply with these new emergency preparedness regulations [2]. ([https://www.federalregister.gov/documents/2016/09/16/2016-21404/medicare-and-medicaid-programs-emergency-preparedness-requirements-for-medicare-and-medicaid](https://www.federalregister.gov/documents/2016/09/16/2016-21404/medicare-and-medicaid-programs-emergency-preparedness-requirements-for-medicare-and-medicaid)).

The large numbers of the patients requiring care immediately after a disaster, the continued flow of patients during a prolonged disaster, and the loss of hospital infrastructure as a result of a disaster all have the potential to overwhelm hospital resources. A hospital’s surge capacity refers to “the ability to provide adequate medical evaluation and care during events that exceed the limits of the normal medical infrastructure of an affected community [3].” To provide adequate surge capacity and maintain medical system resiliency during disasters, hospitals, and communities must have medical preparedness plans, as well as carefully planned command and control systems that efficiently manage the medical responses.

Local Community Medical Response

Incident Command Systems

In the United States, the National Incident Management Systems (NIMS) provides a framework for disaster response by hospitals and local governments [4]. This includes the requirement that both hospitals and communities have an Incident Command System (ICS) [5]. In general, ICS uses a modular system with a single incident commander (IC) who directly supervises a variable number of subsections. A typical ICS includes five principal components:

1. **Leadership**—This is the command section, chaired by the leader of the response effort (the IC). The IC is supported by special staff, such as public affairs, safety, legal counsel, and others as needed.

2. **Operations**—This section oversees and coordinates the immediate response and ongoing operational activities. This tends to be the most
active section during a disaster.

3. **Planning**—This section assesses the potential for future events, develops contingency plans for future events, and plans timelines for the deployment of critical resources. These planning activities permit the operations branch to focus on managing the response to active events.

4. **Logistics**—This section focuses on the logistical support that every event requires, including equipment, personnel, supply, and infrastructure support.

5. **Finance**—This section accounts for and manages all money that is spent during the response to a disaster. Although immediate costs and purchases during a disaster may be supported by affected communities and hospitals, accurate purchasing records, inventory records, personnel costs, and transportation costs must be carefully managed in order to recoup costs after the event insofar as possible.

The Hospital Incident Command System (HICS) manages the response within the hospital and coordinates the hospital’s efforts with the overall community response. Similar to the community IC, the HICS is also led by hospital IC from within the hospital’s existing leadership structure. The hospital’s IC and the community IC communicate with each other directly or via liaison personnel. The organization and leadership of the HICS are usually different than the organizational structure and leadership of day-to-day hospital operations [6]. Hospitals, including their intensive care units (ICUs), must assign personnel to specific HICS positions as part of their disaster preparedness planning. Each individual assigned to an HICS position has specific duties that must be performed prior to, during, and following the disaster response. It is imperative that all HICS personnel be fully trained for the duties they are required to perform.

During day-to-day hospital operations, different ICUs often function as individual, independent silos. During a disaster scenario with limited resources, these ICUs must coordinate patient movement and resource utilization, and do it quickly often without typical infrastructure in place. The American College of Chest Physicians (ACCP) Taskforce for Mass Critical Care recommended in their 2014 guideline document the specific inclusion of a new HICS position to lead this ICU coordination: the Critical Care Team Leader (CCTL). The primary role of the CCTL would be to facilitate horizontal coordination across all ICUs and between ICUs
and other areas of the hospital. The CCTL should communicate directly with hospital IC and all ICUs, as well as with inflow/outflow points such as the ED, OR, and wards. The CCTL is critical to create a coordinated emergency mass critical care response.

**Surge Capacity**

*Surge capacity* refers to the ability of a hospital or other health care system to expand its normal operating capacity in the setting of an emergency. The key aspects of surge capacity can be summarized as “stuff, staff, and space.” Inadequacy in any of these three categories will reduce a hospital’s ability to surge optimally in a disaster. The American College of Chest Physicians (ACCP) Task Force for Mass Critical Care (henceforth referred to as “the ACCP Task Force”) provides a classification system for differing levels of surge response in their 2014 guidelines on the management of the critically ill during disasters and pandemics [7]:

*Conventional capacity:* In this category of surge response, the hospital should be able to increase its critical care capacity by approximately 20% above its normal limitations. This level would be implemented during major mass-casualty incidents that trigger activation of the hospital emergency operations plan. Most facilities should be able to achieve this level of response using existing staffing and resources, including strategies such as cancellation of elective procedures and transferring of appropriate patients out of ICUs [8].

*Contingency capacity:* This level would be used temporarily during a major mass-casualty incident, or on a longer-term basis during a disaster whose medical demands exceeded routine hospital and community resources. This level of response implies the need to increase a hospital’s critical care capacity by 100% and may require the use of alternate hospital resources for the provision of critical care, for example, the use of postanesthesia care unit spaces and staff [9]. In general, the level of medical care provided at this degree of surge response would be within the usual community standards.

*Crisis capacity:* This level would be implemented during catastrophic situations that result in a significant impact on the standard of medical care that can be provided. Examples of such an event, which implies a 200% increase of the critical care demand on a hospital, include a prolonged pandemic, a natural disaster with extensive destruction of infrastructure, a large-scale terrorist attack, or a prolonged violent conflict. Severe limitations of space, staff, and supplies would not allow hospitals to provide the usual standard of medical care. At the crisis
level, institutions will need to consider triage principles, rationing of care, and other potential ethical challenges while maximizing their ability to provide the best possible care to the greatest number of the patients.

Hospitals and their critical care units should develop disaster preparedness plans that contain specific criteria for each level of surge capacity. Identical disasters might have very different effects on different hospitals, depending on an institution’s size and mission. For example, an eight-victim automobile crash may require a conventional level of surge capacity for a large hospital that includes a level 1 trauma center, but could require a contingency or crisis level of surge capacity for a small community hospital.

During contingency and crisis capacity scenarios, a hospital may need to optimize its resources in order to maximize its ability to care for those patients in greatest need. Several state and local governments in the United States, in collaboration with the Office of Public Health Preparedness and Response at the CDC, have developed plans based on the Modular Emergency Medical System (MEMS) framework. MEMS provides a method for a community to manage a surge of patients who require screening, triage, antibiotic treatment, immunizations, prophylaxis, or noncritical inpatient care. By providing temporary facilities for noncritical care, hospitals can redirect resources towards higher-acuity patients.

The major MEMS components are Neighborhood Emergency Help Centers (NEHC) and Acute Care Centers (ACC). Both types of centers can provide screening and triage. The NEHC provides routine, nonurgent outpatient care. The ACC can provide inpatient care to acutely ill noncritical patients. The ACC can receive patients directly from an incident or permit hospitals can offload stable inpatients in order to free up hospital critical care bed space during overwhelming events. Local or regional authorities can open an NEHC or an ACC under two scenarios: (a) when a federal public health incident or a federal disaster is declared or (b) when the state governor has issued a state of emergency. Both types of temporary facilities will operate under the command and control of the local community ICS with support from a Regional Multiagency Command [10]. A carefully executed MEMS plan allows hospitals to offload stable patients to an ACC, preventing the hospital from being overwhelmed during a disaster and allowing the hospital to expand its critical care capabilities by utilizing non-ICU hospital beds for critical care, when necessary.
CRITICAL CARE DURING DISASTERS

During a major disaster, nothing will challenge hospitals more than attempting to provide high-quality critical care with limited resources. The Hospital Preparedness Program (HPP) of the U.S. Department of Health and Human Services spends approximately $255 million per year, or over $4 billion since 2002, in grant support to local institutions to enhance their ability to respond to disasters, including improvements of surge capacity [11]. A 2008 report by the U.S. Government Accountability Office indicated that many states were not adequately prepared to respond to a major catastrophe, such as an influenza pandemic [12]. A follow-up report in 2013 indicated that US hospitals receiving HPP funds have made some improvements of their disaster planning, but shortcomings still persist in the number of emergency medical volunteers, decontamination systems available, and hospital bed count notification to coordinating authorities [13].

Disasters requiring critical care resources include massive trauma events, such as natural disasters, transportation-related accidents, or violent trauma such as deliberate explosions or mass shootings. Since the 2003 SARS outbreak in Toronto and the 2009 to 2010 H1N1 influenza pandemic, greater attention has been paid to disease outbreaks as a form of disaster for hospitals, especially for their long-term impact on critical care. Lastly, disasters may affect hospitals through destruction of the hospital infrastructure itself, such as during a hurricane or earthquake, or by illness or injury that afflict the hospital staff; in both scenarios, the mission of the hospital can be impaired at a time when it is needed most.

These three categories of disaster (trauma, epidemic, and degradation of hospital functions) can and do co-exist. The 2010 earthquake in Haiti led to the immediate death of 230,000 people, but the mass trauma was followed by a cholera epidemic that affected 352,033 during 2011 alone. The devastation to Haiti’s medical system, already fragile before the quake, further impaired that country’s ability to cope with the other two disasters [14]. Conversely, it is estimated that the case-fatality rate of the 2003 SARS epidemic was reduced from a predicted 20% to the actual rate of 6.5%, despite some shortcomings noted by advance planning efforts [15,16].

As of 2010, there were an estimated 103,900 critical care beds in the United States, a 17.8% increase from 2000 despite a 2.2% decrease in the
total number of staffed hospital beds [17]. The bulk of this growth has occurred in academic medical centers and other large hospitals, suggesting that potential surge capacity may be limited at smaller, nonteaching hospitals [18]. Mean ICU bed occupancy in the US was 68.2%, and on average 39.5% of the patients in US ICUs required mechanical ventilation at any given time [19]. The ratio of ICU beds to population (approximately 20 beds/100,000 residents) is relatively high in the US; the Canadian Critical Care Trials Group in 2014 identified 3,170 ICU beds and 4,982 mechanical ventilators available for patients in Canada, with a ratio of 9.5 beds/100,000 residents [20]. Among other developed countries, Australia, New Zealand, and the United Kingdom maintain bed ratios comparable to that of Canada, while Taiwan, Belgium and Germany exceed the US in their numbers of beds per population [21–23].

Of special note, a disproportionate paucity of pediatric critical care resources would exist should we become resource limited during a disaster. In 2010, there were only 4,044 PICU beds in the United States (3.9% of all 103,900 critical care beds listed above), yet 24% of the population was pediatric (0 to 17 years old). This relative scarcity of pediatric critical care resources may present unequal access to care for children as compared to adults during disasters, a time when children often are disproportionately affected. Creative problem-solving, such as sending adolescents and large grade-school children to adult ICUs with just-in-time training and simple color-coding tools for adult providers or repurposing some of the 20,000 NICU beds that exist in the United States for disaster-affected infants 0 to 12 months old, could be two potential ways to improve access to pediatric critical care during disasters, but such changes would require system-wide coordination [21–23].

Overall, these data suggest that hospitals of developed countries have a consistent, although uneven, ability to expand their critical care capacity during a disaster. However, even with normal excess capacity, there may not be a sufficient number of critical care beds to meet the demands of a pandemic that might affect the entire nation at the same time. Critically ill patients who are not admitted to an ICU have a three- to fivefold greater mortality rate compared with those who are cared for in an ICU [24]. Thus, if critical care capabilities become overwhelmed by large numbers of critically ill or injured patients during a disaster, high mortality rates will likely occur.

**Surging Assets to Optimize Critical Care Capability**

When planning for surge capacity during disasters, hospitals need to prepare for events that have a sudden impact and are of relatively short
duration, such as transportation accidents and explosions, as well as more prolonged events, such as natural disasters and pandemics [3,5]. The ACCP Task Force identifies three key elements of planning critical care surge capacity [7,25]:

*Stuff*: the medical supplies and equipment necessary for providing critical care.

*Staff*: the availability of trained critical care providers and support personnel.

*Space*: the physical space within (or rarely outside of) the hospital that can be used to provide critical care to a large number of critically ill or injured patients.

### Stuff

Patients are generally admitted to ICUs because of monitoring needs, the need for intensive-care nursing, or the need for treatments with special equipment or medications. The provision of mechanical ventilation is the most common requirement needed to manage critically ill patients with respiratory compromise. The main challenge of providing this important therapeutic modality during a disaster is the availability of mechanical ventilators.

During a major influenza pandemic, demand for mechanical ventilators in the United States could increase by 60,000, assuming a 30% attack rate and a high case-fatality rate of 0.25% to 0.5% [26]. The United States has approximately 62,000 full-feature ventilators, or 20 of these per 100,000 residents, plus an additional 100,000 ventilators with fewer features but which could be used during a disaster [27]. Of these 100,000 “extra” ventilators, however, it is estimated that the US could utilize no more than 56,000 additional ventilators due to limitations of the numbers of trained respiratory therapists [28]. Thus, in preparing to provide mechanical ventilation to a large number of critically ill disaster casualties, planners need to consider other options, such as high-flow nasal cannula oxygenation or noninvasive positive-pressure ventilation for selected patients. Anesthesia machines and transport ventilators could serve as additional options, although these could be similarly limited by the number of trained personnel and have disadvantages with regard to infection control [29–32].

The provision of critical care during a disaster will also require that a large quantity of supplies and pharmaceuticals be on hand and readily available to critical care providers. The Joint Commission currently requires that accredited hospitals plan for 96 hours of autonomous function, without external resupply, in the event of disaster (although 96
hours of supplies and the ability to function at full capacity are not required). In 2005, during the Hurricane Katrina disaster in New Orleans, the lack of available supplies, pharmaceuticals, and operational equipment forced the dedicated staff at Charity Hospital to improvise critical care practices and deviate from the usual standards of care prior to final evacuation of the hospital [33]. Hospitals in areas affected by the Great East Japan Earthquake and subsequent tsunami of 2011 and by Hurricane Sandy in 2012 showed comparable experiences. In Miyagi Prefecture in Japan, for example, six out of 14 of hospitals had less than 1 day of food on hand at the time of the quake, and another six hospitals had less than 1 day of medical supplies. Just-in-time supply practices at New York City hospitals produced some similar shortages, offset in part by supplies available from elsewhere in the city [34,35].

Figure 127.1 provides recommendations from the ACCP Task Force on means to conserve supplies at differing levels of surge response.

**FIGURE 127.1** Methods for optimizing available supplies in differing degrees of surge response during disasters.

**Staff**

A significant challenge of maintaining critical care capability during a disaster will be the availability of a sufficient number of trained personnel. Shortages of intensivists, critical care nurses, respiratory therapists, critical care pharmacists, and other specially trained personnel may be a limiting factor in caring for large numbers of critically ill patients. In infectious outbreaks or natural disasters, hospital staff may
themselves be victims, further decreasing the institution’s ability to respond [36,37]. The ACCP Task Force’s 2014 consensus statement endorsed prior recommendations on the surging of staff [25,38]. These recommendations state that experienced providers should perform direct patient care, when feasible. Those providers not normally operating in critical care settings should be cross-trained, or retrained, on essential bedside skills in the ICU as part of a hospital’s disaster preparedness program. Finally, systematic procedures (such as protocols) should be instituted and understood by all critical care providers, in order to standardize processes, maximize good outcomes, and maximize safety to patients and staff during a disaster.

During contingency and crisis surge conditions, intensivists will need to focus part of their effort on supervising cross-trained physicians from other specialties. Nonintensivist physicians who are skilled in providing hands-on care, such as hospitalists, emergency physicians, general surgeons, or anesthesiologists, could be assigned six patients each (assuming that other urgent clinical duties do not take precedence). Intensivists could supervise four to eight such providers, thereby extending their critical care coverage to almost 50 patients.

Comparable models have been proposed for critical care nurses supervising non-CCRN, critical care pharmacists supervising other pharmacists, and so forth. During a crisis surge scenario, standard patient ratios may not be achievable. ICU charge nurses could match several non-ICU nurses to appropriate patients, leaving only the most complex patients under the sole care of other ICU nurses. Specific bedside care procedures could be assigned to non-ICU nurses (bathing, vital signs, catheter management, medication delivery, among others), thereby permitting ICU nurses to oversee the provision of specific critical nursing care to several patients. Respiratory therapists usually provide care to four to six ICU patients, but surge requirements may mandate a higher ratio of patients per therapist, ICU therapists supervising outpatient or non-ICU therapists, or even ICU therapists directing nontherapists in basic care. Finally, oncology, outpatient, or other non-ICU pharmacists may similarly be asked to support operations under the tutelage of critical care pharmacists. Training for such processes will become necessary for prolonged events that will severely strain staff resources during a major disaster [25,38].

**Space**

It is important to remember that critical care is a concept, not a location. During a major disaster, space limitations may require that critical care be provided in other areas of a hospital [24,39]. When it becomes necessary to provide critical care outside of an ICU during a major
disaster, it should be provided in those areas of a hospital that are most analogous to an ICU in medical function.

In the initial phases of a surge requirement, hospitals should be able to accommodate up to a 20% increase of critically ill patients with minimal impact, assuming that supplies and staff are available and the hospital is not at maximum capacity. Stable ICU patients requiring minimal care or monitoring can be transferred to step-down units, telemetry areas, postanesthesia care units, or other settings as appropriate. Total hospital bed space should be decompressed by transferring stable ward patients to home care, to skilled nursing facilities, or to alternate community facilities such as an ACC. As an emergency mass critical care event progresses, formal critical care space will need to expand into other areas of the hospital, with the hospital continuing to make room for critically ill patients by transferring the most stable inpatients elsewhere.

An alternative to expanding internal ICU capability is for communities to develop and deploy “field” ICUs. Critical care has been provided in such settings before, with recent experience in New York City following the damage to Bellevue Hospital by Hurricane Sandy as well as during humanitarian international missions or military operations [25,40,41]. However, because of the logistical requirements for specialized equipment, infection control support, and the relocation of trained personnel, critical care should only be provided in “field” settings as a last resort. For most major disaster situations, such facilities can be best used for the management of noncritically ill patients who are transferred from hospitals in order to free up space for the management of the critically ill. The 2014 ACCP Task Force recommends using alternate sites for patients requiring less-intensive management, thus permitting the expansion of critical care services within the hospital; deployable, “field”-style ICUs are to be used for critical care as a temporizing measure pending transfer to safer locations [25].
RESOURCE ALLOCATION AND TRIAGE DURING TIMES OF OVERWHELMING DEMAND

The Greatest Good for the Greatest Number

The goal of surging critical care resources during a disaster is to provide the greatest good for the greatest number of event victims. Critical care providers and institutions should strive to manage resources within their own facility and region with the goal of providing usual critical care practices to the extent possible. However, in a major disaster, because resources become increasingly limited, health care providers and leaders must have a plan in place to change the focus of critical care from the needs of the individual to the needs of the population as a whole. This requires a defined triage plan to be developed, communicated, and implemented fairly.

Ethical and Legal Principles

Utilitarian principles guide the theory of the “greatest good for the greatest number.” In times of overwhelming resource constraints, limited capabilities should be targeted to those with the greatest likelihood of benefiting from the care. Those who are unlikely to recover or improve with the available care are not abandoned, but are provided with appropriate palliative care. This fundamental principle guides the implementation of a mass-casualty triage system during major disasters [42,43].

The ACCP Task Force supports the concept that when surge measures do not meet demand, then individual autonomy may be limited. It mandates a fair and just rationing of resources, based on objective information and decision-making, in order to benefit the population as a whole, rather than individual patients. Such a shift in health care priorities requires active community involvement and an open, transparent decision-making processes. Ideally, plans for the fair and just rationing of critical care resources during periods of overwhelming demand should be developed prior to the disaster.

Importantly, in order to implement such processes, providers must feel secure in their legal protection. Hence, providers should be legally protected from local and state law if there is a need to deviate from the usual standards of care during periods of scarce resources. The ACCP
Task Force recommends that uniformly accepted, predetermined algorithms be developed for triaging critically ill patients during a disaster, with adherence to these algorithms being sufficient to provide necessary legal protection to providers and other decision-makers [42]. The need for such legal protection was poignantly highlighted in New Orleans during the Hurricane Katrina disaster, as palliative care was provided to some patients as evacuation attempts were repeatedly delayed and hospital capabilities were overwhelmed [44]. In response to these events, New York State has developed ventilator allocation guidelines for pandemics and other mass-casualty events, with other states now following its lead [45]. Notably, critical care providers should not implement triage and resource allocation processes without the direction and support of their hospital administration through HICS.

**Critical Care Triage**

There remains debate about the preferred method of triage during a major disaster where patient needs have exceeded critical care resources. It would be difficult to develop a single uniform triage method for all potential scenarios. In the specific setting of ventilator allocation for pandemic influenza, controversy persists regarding the most equitable form of patient selection, including first-come-first-serve, the use of PaO$_2$/FiO$_2$ ratios, or the Simple Triage Scoring System (STSS) [46–48]. Although each of these concepts has its merits; none have been prospectively evaluated in a disaster setting.

The ACCP Task Force recommends that planning for the triage of critically ill patients during a major disaster should include well-defined “triggers” that promptly alert hospital and community leadership to the fact that critical care resources are being overwhelmed and there is a need to direct the use of a triage process. Such triggers would include a lack of critical equipment or medical supplies, inadequate critical care spaces, inadequate staff, and inadequate capability to transfer noncritically ill patients to other facilities.

Once the requirement to triage care has been directed, critical care providers must determine which patients should receive critical care and which patients should not. This process needs to be carefully planned and evaluated with community involvement prior to a catastrophic event. If, for example, a health care system or region proposes to exclude critical care to the very elderly during a major disaster, then community representatives from the elderly population would need to be included in such decisions. That is, the elderly would participate in advance planning with providers on how to triage the elderly during future mass-casualty emergencies.

Several severity-of-illness models have been developed for the ICU
setting that may be applied to the triage process. However, all have similar limitations in that they have not been rigorously evaluated in emergency mass critical care scenarios. The Task Force and other groups have advocated the use of the Sequential Organ Failure Assessment (SOFA) score because of its demonstrated effectiveness for the ongoing assessment of critically ill patients and the ease with which it can be calculated with minimal laboratory requirements [42].

The ACCP Task Force recommends that hospitals establish a triage system in advance of a disaster, with either a designated triage officer or triage team who will make decisions based on predetermined guidelines. A triage team, consisting of an experienced intensivist and another acute care physician, may be preferable to a single triage officer, given the emotional burden and the utility of a second “set of eyes” during a crisis. This group, operating independently from the bedside clinicians, would gather periodic patient data to determine the severity of illness and document improvement, stability, or deterioration of critically ill patients over time. The patients who deteriorate or fail to improve over time would have their critical care resources reallocated to other patients (Fig. 127.2). The ACCP Task Force proposes that the patients with a predicted mortality of >90% not be offered critical care; a prior recommendation to withhold critical care from patients with SOFA scores >11 has since been revised due to conflicting data about the significance of such a score during pandemic influenza [42,49]. The availability of an experienced critical care triage team has the advantage of removing the burden of triage decisions from busy clinicians who are providing critical care at the bedside. This team also removes some of the inherent bias that providers may have when making decisions for patients personally known to them. In the HICS, the critical care triage team should operate under the command of the Hospital Operations Section Chief.
In order to assure compliance and integrity of the triage process, a review committee should be established to oversee triage plans and operations. This committee, distinct from the triage team, would:

- Work with regional planners and maintain situational awareness of the community and state, regarding the ongoing use and need of triage protocols.
- Review the implementation of the local triage protocol, to ensure compliance and integrity of triage operations.
- Serve as a forum for appeals by patients, families, and staff regarding the accurate and ethical implementation of the triage tool.
- Participate in the real-time epidemiological evaluation of the catastrophic event, to help public health and other officials determine the ongoing validity of SOFA scoring as a triage tool for critically ill patients.

**FIGURE 127.2** Critical care triage algorithm.
Preparation for disasters requires a methodical approach within a defined organizational structure in order to optimize care for large numbers of critically ill patients. Ideally, hospitals are the optimal setting to provide critical care for severely ill and injured patients. During major disasters, hospitals should coordinate with community medical response systems to offload patients with minor injuries or illnesses so that hospital resources can be focused on the care of critically ill patients.

Predisaster planning and training are essential for mitigating the adverse effects of an overwhelming disaster on hospitals and their communities. Carefully developed plans for surging critical care resources will facilitate continuation of usual hospital processes for the largest number of the patients. However, when surge procedures fail to meet the critical care demands of an overwhelming patient influx, processes to triage and alter the usual standards of critical care must be implemented. These planning concepts and guidelines can help guide critical care practitioners to care for their patients under the challenging conditions of a catastrophic disaster.

Chapter 128

Chemical Agents of Mass Destruction

JAMES GEILING • RANDY WAX • LAWRENCE C. MOHR JR

If supposedly civilized nations confined their warfare to attacks on the enemy’s troops, the matter of defense against warfare chemicals would be purely a military problem, and therefore is beyond the scope of this study. But such is far from the case. In these days of total warfare, the civilians, including women and children, are subject to attack at all times [1,2].

Chemical agents of terror have moved to the forefront of concern for health care providers as weapons of mass destruction (WMD) have become readily available to both domestic and international terrorists. Critical care physicians must be familiar with these agents, their impact on patients, and the potential dangers these compounds can cause to health care workers.

Although terrorists have traditionally focused their efforts on the use of conventional explosives, chemical agents have emerged as attractive weapons of terrorism for a variety of reasons:

Raw materials for their production are readily available throughout the world.

Raw materials are inexpensive.

A chemical weapon of mass destruction can be produced with relatively small amounts of raw materials.

They may be odorless, colorless, and tasteless.

They are difficult to detect.

They do not destroy infrastructure.

They possess a latency period between the time of exposure and the
development of clinical symptoms. Their use produces a mass media response [3].

The events of September 11, 2001, and subsequent terrorist threats have changed the nature of physician training and preparation requirements. Whereas most physicians have prepared for mass casualty events from multisystem trauma, as in transportation accidents, they now must know how to provide mass care to victims following a WMD event. This chapter focuses on the recognition and management of patients exposed to common chemical agents of mass destruction.

HISTORY

Chemical agents of mass destruction are gaseous, liquid, or solid substances that are employed against a population because of their direct toxic effects. Virtually any toxic substance can be used as an agent of mass destruction. However, those that have been successfully weaponized are characterized by ease of production, ease of handling during weapon assembly, dispersion properties, and ability to cause injury and death at relatively low concentrations [4].

Although the first reported use of chemical agents dates back to 1000 BC when Chinese forces used arsenical smokes, the use of chemical agents for warfare began in earnest during World War I when German forces seeking a breakout from the stalemate of trench warfare released 150 tons of chlorine gas on April 15, 1915, near Ypres, Belgium, resulting in 800 deaths and the retreat of 15,000 Allied troops, largely because of the psychologic terror produced by the attack.

The next major use of chemical weapons took place more than 2 years later, on July 12, 1917, again near Ypres, when German forces attacked Allied troops with artillery shells containing sulfur mustard. Although many of the 20,000 casualties had debilitating injuries, less than 5% of the troops died as a result of the chemical attack. Persistent and nonvolatile, sulfur mustard caused a host of new problems for Allied forces, including a latency period before the effects appeared and the need for men, and their horses, to wear protective overgarments [5].

The Geneva Convention of 1925 banned the use of chemical warfare agents because of the physical and psychologic trauma they imposed on their victims.

Nerve agents appeared in the 1930s when the German industrial
chemist, Dr. Gerhard Schrader, began research into the development of stronger insecticides, the first two of which were tabun and sarin. German forces stockpiled these for use in World War II, but never used them.

Chemical agents were used sporadically in the second half of the twentieth century. The United States used defoliants and riot-controlled agents in Vietnam. Iraq used mustard, tabun, and eventually sarin against Iran in the Iran–Iraq war of the 1980s. Later in the 1980s, reports implicated Iraq in the use of cyanide against the Kurdish population of northern Iraq [6].

The Aum Shinrikyo religious cult released sarin gas on two occasions in Japan in the 1990s. The first took place on June 27, 1994, in Matsumoto and resulted in 600 persons exposed, 58 admitted to the hospital, and seven deaths [7]. The more famous and larger event took place the following year, on March 20, 1995, when they released sarin gas in the Tokyo subway system during rush hour. The subway system attack resulted in the deaths of 11 commuters and the medical evaluation of approximately 5,000 individuals [8].

In 2002, Chechen separatists overtook a Moscow theater, taking over 800 hostages. Four days later Russian Special Forces fumigated the building with a derivative of the narcotic fentanyl. Although this method broke the siege, all but two of the 41 terrorists and 129 hostages died from opiate toxicity [9].

The most recent use of chemical weapons occurred in the early morning hours of August 21, 2013 in the Ein Tarma and Zamalka suburbs of Damascus, Syria. Social media reports and videos as well as satellite imagery demonstrated large numbers of sick adults and children with no visible trauma; medical personnel described the symptoms as most consistent with exposure to a nerve agent [10]. Three Damascus hospitals received over 3,000 casualties where the principle antidote atropine was in short supply and exposure to contaminated patients at one hospital resulted in 41 staff members, including 10 doctors, becoming contaminated [11]. The attack killed approximately 1,429 people, including 426 children [12].

In 1993, the Chemical Weapons Convention (CWC) went into effect as an international treaty that bans the use, development, production, acquisition, transfer, stockpiling, and retention of chemical weapons by signatory nations. At the time of this writing, the CWC was ratified by 192 nations, including the USA; North Korea and Egypt have not done it. The CWC is administered by the Organisation for the Prohibition of Chemical Weapons, which conducts regular inspections and monitors compliance with provisions of the treaty [13].
DETECTION AND DECONTAMINATION

Initial steps for the management of chemical agent casualties include detection of the chemical agent used during the attack and the decontamination of casualties. Detailed discussions on detection and decontamination are beyond the scope of this chapter. However, hospital-based critical care physicians should understand basic concepts of these topics to better care for their patients and protect themselves and their facilities from potential harm.

The most important tool for detecting the use of these agents is accurate and timely intelligence from military or law enforcement agencies. Unfortunately, hospitals are not usually in the information-sharing and decision-making circles with these groups. As a result, initial awareness of a chemical agent attack typically occurs with the first patient presenting to the emergency department. Hospitals and physicians can improve their preparedness for the management of chemical agent casualties by actively participating in disaster-planning activities at their respective communities.

Various types of sensing devices can be used for the detection of chemical agents in the environment. At the present time, all commercially available detection equipment uses point source technology; that is, proximity to the substance is required. The handheld Chemical Agent Monitor uses ion mobility spectrometry to detect mustard and nerve agents. Chemical agent detection papers, such as the M8 and M9 papers (Anachemia, Lachine, Quebec, Canada), can be used to detect mustard and nerve agents. The M256 Detection Kit (Anachemia, Lachine, Quebec, Canada) can detect mustard, nerve agents, phosgene, and cyanide. Standoff capability, that is, detecting agents from as far away as 5 km, has been developed to detect contaminated areas without being exposed [14]. Many of the readily available detection strategies cannot detect lower levels of chemical agent, thus being less useful to confirm successful decontamination or detect chemical agents remotely from the site of exposure. Most hospitals will not have capability to confirm exposure or nature of chemical agents used in a timely manner to influence patient care or protect their facilities.

As health care providers, use of samples from patients rather than environmental sampling may be helpful for clinical and forensic purposes. For example, dilute traces of chemical agent metabolites of sulfur mustard (HD), sarin (GB), soman (GD), VX, and Russian VX (RVX) can be detected in urine samples from exposed patients using fast liquid chromatography–tandem mass spectrometry [15]. Sulfur mustard exposure can also be determined from hair analysis of patients with
suspected exposure [16]. Further development of rapid, easy, and affordable technology to help hospitals detect and identify chemical weapon agents is expected to make new technologies available.

Ideally, the decontamination of chemical agent casualties should be accomplished by first responders or hazardous material personnel prior to evacuation or transport to a medical facility. Unfortunately, most disaster victims bypass emergency medical system transport and arrive unannounced at the closest hospital. As a result, hospitals must be prepared to decontaminate chemical agent casualties prior to admission. Facilities and protocols to decontaminate such casualties should be developed by all hospitals. Such processes are needed to protect the victims from further exposure and to prevent the spread of chemical agents within the hospital and among health care providers.

Critical care physicians, nurses, and support personnel may be called on to help develop decontamination protocols and assist in the decontamination process. It is imperative that all individuals designated to serve on decontamination teams be thoroughly trained in the procedures, precautions, and protective clothing required by the decontamination process. Attempting to provide help in a contaminated environment without prior training puts the health care provider at risk of being exposed to a chemical agent and could impede the delivery of effective medical care for the victims of a chemical attack. One common (and potential fatal) error made by health care providers is to rely on personal protective equipment effective for protection from biologic hazards (such as N95 respirators) which provide insufficient protection during decontamination or care of contaminated chemical agent exposed casualties.

The sarin gas release in Tokyo provides a clear example of the need for preparation and training prior to a chemical attack. Of the 1,364 emergency personnel who responded to the attack, 135 (9.9%) became symptomatic and required medical support themselves. None of the first responders wore protective clothing or face masks and off-gassing of the chemical agent from clothing of victims played a significant role in their complaints. These effects were evident among hospital staff as well first responders. It was reported that 23% of the staff at the hospital that received the patients also experienced symptoms [17].

The Occupational Safety and Health Administration (OSHA) mandates that all health care providers be trained to perform their duties without jeopardizing the health and safety of themselves or coworkers. It provides guidance for the use of personal protective equipment and requires that
written plans be developed for hospitals to train teams for the use of personal protective equipment to receive contaminated victims [18]. Most medical facilities prepare their decontamination teams to operate in OSHA personal protective equipment Level C; that is, full-face mask with an air-purifying canister respirator and chemical-resistant clothing. Recurrent training and drills in the use of available and appropriate personal protective equipment by hospital staff is recommended to ensure readiness in the event of a chemical agent event.

Decontamination strategies for chemical exposure can include mechanical removal of agents (e.g., washing or wiping), chemical deactivation, or a combination of both approaches. Mechanical removal without deactivation may result in spread of some agents at the decontamination area and create contaminated waste. Chemical deactivation may be generic or specific for certain agents. For most situations, effective chemical decontamination can be performed by carefully removing the victim’s clothing and thoroughly washing the victim with soap and water. It has been reported that removing contaminated clothing alone can eliminate 85% to 90% of chemical contaminants [19]. Use of specific solutions to facilitate decontamination, such as 0.5% hypochlorite solutions, may be less useful than water/soap strategies given the potential delay of preparing and deploying specialized solutions.

The M291 Skin Decontamination Kit has been in use by the military for many years, and can facilitate mechanical removal and partial deactivation of some agents. Newer technology, such as Reactive Skin Decontamination Lotion (RSDL) (O’Dell Engineering Ltd/E-Z-EM Canada Inc., Canada) may be superior [20]. It is not used for prophylactic protection or total body decontamination, but, if applied early following exposure, is effective for neutralizing chemical warfare agents and T2 mycotoxins [21]. However, during exposures associated with trauma, RSDL may interfere with normal wound healing [22].

In addition to skin and wound decontamination products, other strategies may be used to decontaminate personal protective equipment and external surfaces. For example, FAST-ACT (TIMILON Technology Acquisitions, Fort Myers, Florida) acts as a nanosorbent to adsorb and neutralize chemical agents and is available in a spray powder, pressure bottles, and on the surface of a glove for easy wiping. EasyDECON (Envirofoam Technologies, Huntsville, Alabama) can be used to decontaminate exposed environmental surfaces. Normally employed as a foam, it effectively neutralizes a variety of chemical agents including nerve gases and mustard [23]. A recent study from the Czech Republic provides an excellent example of a comparative approach to chemical agent decontamination strategies, taking into consideration multiple factors relevant to different operating environments and expected
exposures [24].

Finally, medical facilities must consider environmental variables such as wind direction, wind velocity, temperature, and water runoff when setting up decontamination areas. These environmental considerations are important for protecting patients and employees from exposure to chemical agents, as well as minimizing the risk of contaminating buildings and equipment during the patient decontamination process.
CLASSIFICATION OF CHEMICAL AGENTS

Chemical agents are normally classified into broad categories based on their mechanisms of action and physiologic effects. The most common classification scheme divides them into the following categories:

- Nerve agents
- Vesicants
- Cyanide agents or “blood” agents
- Pulmonary agents or “choking” agents
- Nonlethal incapacitating agents

Nerve Agents

Because they are the most toxic, nerve agents are the most feared of chemical agents. All nerve agents are organophosphorus compounds, which inhibit butyrylcholinesterase in the plasma, acetylcholinesterase in the red blood cell (RBC), and acetylcholinesterase at cholinergic receptor sites in the central and peripheral nervous systems. The chemical bond between nerve agent molecules and acetylcholinesterase is irreversible, its activity returning only with new acetylcholinesterase synthesis or RBC turnover (1% per day) [25]. The decrease of acetylcholinesterase activity results in the accumulation of acetylcholine at both muscarinic and nicotinic receptors in the central nervous system and neuromuscular junctions of the peripheral nervous system. Cholinergic overstimulation resulting from the accumulation of excess acetylcholine at these sites is responsible for the clinical manifestations of nerve agent toxicity [26].

After an acute exposure to nerve agents, RBC acetylcholinesterase reflects nervous system acetylcholinesterase activity better than the activity of butyrylcholinesterase in the plasma. The measurement of RBC acetylcholinesterase activity can now be confirmed with commercially available point-of-care testing, assuming that the devices are present and personnel are trained on their usage [27]. However, its measurement is not common at most clinical laboratories.

Several different nerve agents currently exist, each characterized by a unique molecular structure that irreversibly inhibits acetylcholinesterase.
Compounds that were originally developed in Germany have been designated as the “G” series of nerves agents. The “V” series of agents are better absorbed through the skin than the “G” agents and are so designated because they are more “venomous.” The most common nerve agents include:

GA (tabun): ethyl N,N-dimethylphosphoramidocyanidate
GB (sarin): isopropyl methyl phosphonofluoridate
GD (soman): pinacolyl methyl phosphonofluoridate
GF: O-cyclohexyl-methylphosphonofluoridate
VX: O-ethyl S-(2-(diisopropylaminoethyl) methyl phosphonothiolate

The “G” agents are volatile, whereas VX is a persistent, oily substance with better percutaneous absorption. Each of these agents can be dispersed through a variety of weapons and munitions. Inhalation of nerve gas is the most effective means of producing clinical effects, although it can also be ingested. High doses of persistent nerve agents, such as VX, can be absorbed through the skin. The clinical effects of nerve agent toxicity occur as a result of acetylcholine accumulating at both nicotinic sites (autonomic ganglia and skeletal muscle) as well as muscarinic sites (including postganglionic parasympathetic fibers, glands, and pulmonary and gastrointestinal smooth muscles). Nicotinic receptors appear to be most sensitive to the effects of nerve agents, with inactivation of acetylcholinesterase in autonomic ganglia and the neuromuscular junction of skeletal muscle responsible for many symptoms and signs of nerve agent exposure. The typical clinical manifestations of nerve agent toxicity are similar to those produced by organophosphate insecticides, although nerve agents are up to 1,000 times more toxic [26].

The basic clinical syndrome produced by nerve agents can be remembered by the acronym “SLUDGE”: salivation, lacrimation, urination, defecation, gastric distress, and emesis. Alternatively, “DUMBELS” (diarrhea, urination, miosis, bradycardia/bronchorrhea/bronchospasm, emesis, lacrimation, salivation/secretion/sweating) provides a more detailed tool to remember the muscarinic signs and symptoms [28]. Specific signs and symptoms of various organ systems depend on the dose of nerve agent received. Inhalation of a nerve agent usually produces immediate effects that occur within seconds to minutes after exposure. Dermal absorption usually produces delayed effects that can develop at any time between 10 minutes and 18 hours after skin exposure, depending on the dose. Common signs and symptoms for each organ system are summarized
Inhalation of a nerve agent results in the development of rhinorrhea, bronchorrhea, and bronchoconstriction soon after exposure. Dyspnea and chest tightness are common early symptoms. Coughing and wheezing may occur. The volume of airway secretions, the magnitude of bronchoconstriction, and the severity of airway symptoms all increase with higher exposure doses. High-dose or prolonged exposure may result in diaphragmatic weakness and centrally mediated apnea, which can result in ventilatory failure [25,26].

Although vagally mediated bradycardia is the expected heart rate response from cholinergic overstimulation of muscarinic receptors, this is commonly overridden by tachycardia resulting from nicotinic-mediated adrenergic stimulation and hypoxia. First-, second-, and third-degree heart block may occur [25,26]. Prolongation of the QTc interval can precipitate torsade de pointes and has a poor prognosis [29]. Although hypertension may occur as a result of nicotinic-mediated adrenergic stimulation, blood pressure usually remains normal. A decline of blood pressure is typically a sign of impending death [5].

Muscarinic and nicotinic stimulation of the peripheral nervous system results in muscle fasciculations and profuse sweating, respectively. Muscle weakness and muscle paralysis may occur following high-dose exposures. Seizures can develop suddenly. The seizures may resolve spontaneously, but can be prolonged with status epilepticus [25,26]. Smaller-exposure doses typically result in nonspecific neurologic findings including an inability to concentrate, insomnia, irritability, and depression. A variety of psychologic and behavioral changes, ranging from mild confusion to severe anxiety, can also occur [23]. Hallucinations or complete disorientation do not appear. Mild exposure also may result in a slight decline of memory function, as observed in first responders in the Tokyo sarin gas release of 1995 [30]. In the decade since that event, those exposed continue to have mild cerebellar effects and posttraumatic stress disorder [31].

Direct contact of the eyes with nerve agent vapor causes miosis that is usually associated with intense ocular pain. Patients also complain of blurred or dim vision and typically have injected conjunctivae with significant lacrimation.

Nausea and vomiting may be among the first signs of nerve agent toxicity. Abdominal cramping and diarrhea may also occur [25,26].

Unfortunately, few of the clinical signs or symptoms listed here may appear following exposure to a high dose of nerve agent. This is due to the fact that the range of exposure of doses, which produce clinical symptoms, is only slightly less than those which cause death. Therefore, central nervous system collapse with seizures, loss of consciousness, and central apnea may be the first signs of nerve agent toxicity following a
Management of all nerve agent casualties begins with the traditional “ABCs” of resuscitation: airway, breathing, and circulation support. Contaminated patients should be managed in the following order:

- Airway management
- Breathing support
- Circulation and hemorrhage control
- Antidote administration
- Decontamination
- Wound dressing
- Evacuation to a noncontaminated treatment location

Ventilatory failure is the primary cause of death following nerve agent exposure. As a result, airway management and breathing support are extremely important for the management of nerve agent casualties. The nausea and vomiting that these patients typically experience must be considered during their airway management. In this regard, all patients should be considered to have a full stomach. Endotracheal intubation and assisted ventilation are required for the management of ventilatory failure. High airway resistance necessitating the need of pressures up to 50 to 70 cm of water may complicate ventilatory support. Because of high airway pressures, if a cuffed endotracheal tube cannot be placed, a double-lumen Combitube (Tyco Healthcare, Pleasanton, CA) is preferable to a laryngeal mask airway. Once an effective airway has been established, ventilatory assistance can be provided by manual ventilation using a bag-valve device or by mechanical ventilation. Nebulized ipratropium can be used for the treatment of bronchospasm that may, in turn, result in decreased airway resistance. Frequent suctioning is necessary to remove the copious airway secretions associated with nerve agent exposure. The use of depolarizing neuromuscular blocking agents during ventilatory assistance should be avoided.

The principal antidote for nerve agents is atropine. Atropine is an anticholinergic drug that blocks acetylcholine receptor sites. As a result, atropine blocks the pathophysiologic effects of the excess acetylcholine that accumulates as a result of nerve gas exposure; it is most effective at muscarinic sites. Atropine is primarily used for the purpose of drying up
the copious airway secretions that patients develop following nerve agent exposure. The standard adult dosing regimen is 2 mg, administered intramuscularly, every 5 to 10 minutes, titrated to the patient’s secretions. The recommended pediatric dose is 0.05 mg/kg, with a minimum dose of 0.1 mg, administered intravenously every 2 to 5 minutes, titrated to effect [26,33]. Among severe cases, adult patients may require 10 to 20 mg of atropine in the first hour to control secretions. The administration of atropine to a hypoxemic patient could precipitate the development of ventricular fibrillation. Therefore, oxygen should be administered and hypoxemia corrected before atropine is given [32,36]. Miosis will not respond to parenteral atropine. Topical tropicamide is effective for the treatment of miosis and the relief of ocular pain [33]. Atropine alone may not be an effective treatment for terminating seizures or reversing ventilatory failure [26,36]. Bulk atropine is available for reconstitution and may be required in the setting of mass nerve agent casualties.

Pralidoxime chloride is the other major antidote for nerve agents. It functions by “prying off” the nerve agent molecule from acetylcholinesterase, thereby rendering the enzyme active again. Unfortunately, it must be given early, before the agent–enzyme bond matures or “ages” which occurs in as little as 2 minutes for soman but takes 3 to 4 hours for sarin. Once the agent–enzyme bond completely ages, the bond is irreversible and pralidoxime chloride has no therapeutic effect. Pralidoxime chloride is only effective at nicotinic sites and, therefore, helps to increase muscle strength. The standard adult dose is 15 to 25 mg/kg or 1 g, given intravenously (in 100 to 250 mL of 0.9% saline) during 20 to 30 minutes. The initial dose may be followed by an infusion of 200 to 500 mg per hour, if necessary. Higher dosing with a 2 g load followed by 1 g per hour for 48 hours has been shown to significantly decrease atropine requirements and the duration of mechanical ventilation for patients poisoned by organophosphate pesticides [37]. The recommended pediatric dose is 15 to 25 mg/kg administered intravenously during 30 to 40 minutes. Severe hypertension is a potential side effect of pralidoxime chloride, and this can be rapidly reversed by a 5-mg intravenous infusion of phentolamine [33].

Atropine and pralidoxime chloride come packaged as two autoinjectors in commercially available kits, called MARK-I Nerve Agent Antidote Kits (Meridian Medical Technologies, Columbia, MD). Each kit contains one AtroPen autoinjector containing 2 mg of atropine and one pralidoxime chloride autoinjector containing 600 mg of pralidoxime chloride. The same company also now produces Antidote Treatment Nerve Agent, Autoinjector (ATNAA), a single autoinjector 2.1 mg of atropine and 600 mg of pralidoxime chloride [38].

Historically, diazepam has been the anticonvulsant recommended for
the management of seizures associated with nerve agent exposure. In the hospital setting, diazepam may be given intravenously. The adult intravenous dose is 5 to 10 mg every 10 to 20 minutes until seizures resolve, but not to exceed 30 mg in an 8-hour period. The pediatric dose is 15 to 25 mg/kg [33]. Autoinjectors that contain 10 mg of diazepam (CANA—Convulsant Antidote for Nerve Agent) are available for use in the field (Meridian Medical Technologies). In both hospital and prehospital settings, health care providers must carefully monitor patients for signs of ventilatory failure following the administration of diazepam. Lorazepam and midazolam that are typically used in a critical care environment are also effective in controlling seizures following nerve agent exposure [39,40]. The use of phenytoin is not recommended [41].

Newer therapies with bioscavengers are currently being investigated as an additional means of mitigating or treating the effects of nerve agents; they can be stoichiometric (cholinesterases) or catalytic (paraoxonase, phosphotriesterase). These enzymes sequester the agent before they reach the cholinesterase targets, thus preventing any “downstream” clinical effects once the esterase has been inhibited. This therapeutic modality may prove most useful for slow-release VX [42,43].

Moderately poisoned patients with systemic signs and symptoms of exposure required 2.5 hospitalization days following the Tokyo sarin gas attack, whereas those on mechanical ventilation stayed over 8 days. Length of stay from the clinical effects of the persistent VX may be mitigated by titrating the need ongoing oxime therapy based upon red blood cell AchE activity [27].

Decontamination remains a key step during the treatment of nerve agent casualties because minimizing exposure to the agent decreases the severity of toxic effects. Removal of all clothing, rinsing the eyes with water or normal saline for 10 minutes, and washing the entire body once with soap and water should suffice. Decontamination should be conducted as soon as possible after ventilatory and circulatory support has been initiated and antidotes have been administered. Rapid decontamination is especially important for nerve agents that can be absorbed through the skin. It is important for health care providers to wear protective clothing and face masks prior to and during contamination of nerve agent casualties [17,25].

Vesicants

The two principal vesicants or “blister agents” are sulfur mustard and lewisite. This section focuses on the more notable sulfur mustard (bis-[2-chloroethyl] sulfide) that is commonly referred to as mustard. Lewisite has similar health effects except for the immediacy of its action in comparison to mustard. It normally takes several hours between contact
with mustard and the onset of signs and symptoms, with the specific latency period depending on the exposure dose. In general, the higher the exposure dose, the shorter the latency period. Mustard is an oily liquid that ranges from clear to pale yellow to dark brown in color. It classically smells like onion, garlic, or mustard, which is allegedly how it got its name. At temperate conditions, it is a persistent liquid that volatilizes slowly. At temperatures greater than 100°F, however, mustard evaporates and mustard vapor becomes a major hazard. As a weapon, mustard will most likely be employed as a contact agent [44].

On entering living cells, mustard alkylates and cross-links DNA causing DNA strand breaks and eventually leading to cell death. Mustard damages any skin that it contacts, resulting in vesicle or bullae formation within 4 to 24 hours after exposure. Vesicle formation typically peaks within several days after contact with the skin; the bullae fluid is not toxic and is therefore not a threat to providers. As the most sensitive organ to low dosage exposures, contact with the eyes may result in painful irritation, conjunctivitis, blepharospasm, and corneal opacity related to edema and pannus formation. Blindness can occur if the corneal pannus is severe and covers the visual axis. Eyelid burns may be first or second degree.

Mild-to-severe airway damage can occur following mustard inhalation with most effects occurring in the upper airways. However, the extent and severity of airway damage is dose-dependent, with lower doses primarily affecting the upper airways and higher doses affecting both upper and lower airways. High inhalational doses can cause a severe inflammatory exudate, pulmonary edema with hemorrhage, necrosis of mucous membranes, mucosal sloughing, parenchymal tissue destruction, and pseudomembrane formation. Sloughed mucosal tissue and pseudomembranes can cause obstruction of the lower airways and serve as a nidus for respiratory tract infections, principally Pseudomonas. Other pulmonary problems include asthma, laryngospasm, acute bronchitis, chronic bronchitis, bronchiectasis, tracheobronchial stenosis, pulmonary fibrosis, bronchiolitis obliterans, and pleural thickening [45–47]. Hypoxia and hypercarbia may occur as a result of ventilation–perfusion mismatching caused by airway mucosal sloughing and hyperreactive or bronchitic airways. Severe gastrointestinal side effects and bone marrow suppression can occur following ingestion of high doses of mustard. Leukopenia with a cell count less than 200 cells/mm³ portends a poor prognosis. Sepsis may occur as a result of leukopenia and the breakdown of skin, respiratory epithelium, and gastrointestinal mucosa [48].
Decontamination is a critical component of the management of mustard casualties. Indeed, decontamination within 1 to 2 minutes after exposure is the most effective means of reducing serious skin and tissue damage from mustard. Because of its persistence, removal of mustard from casualties must occur before admission to a medical treatment facility so health care workers do not become contaminated. In general, the medical care of mustard casualties is supportive. Areas of denuded skin should be treated like burns and liberally covered with silver sulfadiazine ointment [19]. Calamine lotion and topical steroids may soothe mild burning and itching in erythematous areas of skin. Nonsteroidal anti-inflammatory drugs may help to mitigate pain associated with cutaneous inflammation. Cooling the skin to 15°C and applying deferoxamine or zinc oxide may also be beneficial [49,50]. Skin healing following mustard exposure takes longer than skin healing following thermal burns. Some patients may require skin grafts and reconstructive surgery.

Respiratory care is mostly supportive. Bronchodilators may be useful for the treatment of asthma-like symptoms related to hyperreactive airways. N-acetyl-cysteine may not only treat bronchial lesions, but also prevent further injury from oxidative stress. Corticosteroids may also be helpful, but should be used with caution because of the risk of superinfection [51]. Intubation and ventilatory support may be necessary for the management of severe laryngospasm or respiratory failure following high doses of inhaled mustard. Outpatient noninvasive ventilation may mitigate hospital admissions for those with chronic lung disease [52]. Bronchoscopy may be necessary to remove pseudomembrane fragments from the airway. Chronic, progressive tracheobronchial stenosis has been reported following mustard inhalation, and may require periodic bronchoscopy with bougienage or balloon dilation, or laser photoresection to maintain airway patency [53].

For systemic toxicity, early treatment with nonsteroidal anti-inflammatory agents may be useful. Thiosulfate decreases toxicity for animals; also in animal models, granulocyte colony stimulating factor has been shown to reduce the duration of neutropenia by approximately half [54].

In summary, acute mortality is relatively low, but morbidity is high following exposure to a vesicant. The severity and duration of illness and injuries are directly related to the exposure dose and routes of exposure. Because of the persistence of mustard, decontamination is critically important in the management of mustard casualties and for protecting health care workers from being exposed. Victims will consume significant health care resources in the management of their acute care needs and some will require prolonged periods of treatment and rehabilitation for chronic sequelae.
Cyanide

Cyanide can exist either as gas or as a colorless, volatile liquid that easily vaporizes. In both physical states, it typically has the smell of bitter almonds, although 40% to 60% of the population is unable to detect this odor. It is a chemical asphyxiant of the type that is historically classified as a “blood” agent. Cyanide can be used as an agent of mass destruction in two chemical forms: hydrogen cyanide and cyanogen chloride. Although very lethal in high doses, the volatility of cyanide makes it difficult to weaponize, and it ranks among the least lethal of the common chemical agents of mass destruction. Cyanide produces its pathologic effects by binding to iron-containing sites on mitochondrial cytochrome a₃, a key enzyme of the cytochrome oxidase system involved in aerobic metabolism. The binding of cyanide to cytochrome a₃ can occur very rapidly, effectively stopping cellular respiration and forcing affected cells into anaerobic metabolism. Cyanide also has an increased affinity for the ferric ion of methemoglobin that is a property exploited for treatment of cyanide poisoning [55].

The clinical manifestations of cyanide poisoning result from the inability of cells to extract and use oxygen. The onset of signs and symptoms occurs rapidly following inhalation (within 15 seconds), whereas a delayed response of up to 30 minutes follows ingestion. Metabolic acidosis develops as a consequence of increased lactate production from anaerobic metabolism. Compensatory mechanisms to increase oxygen delivery to tissues include tachycardia and increased minute ventilation, which are the earliest clinical signs. Dyspnea may occur as a result of the hyperpnea. Other signs include agitation, anxiety, vertigo, headache, muscle weakness, and trembling. Diaphoresis and flushing sometimes occur. Seizures have been reported. Dilated, unresponsive pupils and coma are late signs of cyanide poisoning and portend a poor prognosis. Without treatment, cyanide victims eventually develop apnea and cardiac dysrhythmias, followed by death from cardiac arrest [55].

Both the administration of specific antidotes and supportive care must be given as soon as possible after exposure to cyanide. Sodium nitrite and sodium thiosulfate are the traditional antidotes used to treat cyanide poisoning. This treatment focuses on detoxifying and excreting the cyanide, as well as on preventing its reentry into the cell. One ampule containing 300 mg of sodium nitrite in 10 mL of diluent (30 mg/mL) is administered intravenously for 2 to 4 minutes to form methemoglobin. The pediatric dose of sodium nitrite is 0.33 mL/kg of a 3% solution given intravenously for 2 to 4 minutes, not to exceed 10 mL. Cyanide binds more effectively and preferentially to the ferric ion site on
methemoglobin in comparison to cytochrome a₃. Therefore, the methemoglobin generated by sodium nitrite removes cyanide from cytochrome a₃-binding sites and frees the enzyme to once again participate in the processes of cellular respiration and aerobic metabolism. Following sodium nitrite administration, 12.5 g of sodium thiosulfate in 50 mL of diluent is administered intravenously at a rate of 3 to 5 mL per minute. The pediatric dose of sodium thiosulfate is 412.5 mg/kg (1.65 mL/kg), given intravenously at a rate of 3 to 5 mL per minute. Sodium thiosulfate acts as substrate for rhodanese, converting the cyanide to thiocyanate that is then excreted in the urine. Sodium nitrite and sodium thiosulfate are very effective antidotes for the treatment of cyanide poisoning when they are given before the cessation of cardiac activity [55,56].

A specific challenge during the management of these patients is in the prehospital environment, specifically in hypoxia environments such as fires or smoke, inhalation where decreased oxygen-carrying capacity can be exacerbated by the induction of methemoglobinemia. Hydroxocobalamin, a precursor of vitamin B₁₂, provides an alternative treatment option for both pre- and in-hospital management. Cyanokit (Dey L.P., Napa CA., www.cyanokit.com) contains two vials of 2.5 g of lyophilized hydroxocobalamin that is reconstituted in 100 cc saline for administration. The standard initial adult dose is 5 g infused over 15 minutes with an additional 5 g given depending on the patient’s condition. Hydroxocobalamin binds with cyanide to form cyanocobalamin that is then excreted in the urine. It is well tolerated with no known major toxicities. Of note, this red molecule results in red mucous membranes, skin, and urine [57]. A major impediment to widespread use of this modality is its cost which is over twice as expensive as the sodium nitrite/sodium thiosulfate kit [58].

Unfortunately, these therapies require intravenous antidote administration and several minutes time before becoming effective. These factors impede their application to large numbers of victims. Thus research efforts have recently focused on developing quick acting, intramuscular antidotes. Sulfanegen, a dimer prodrug of 3-mercaptoppyruvate, serves as a sulfur donor via 3-mercaptoppyruvate sulfur transferase to cyanide, producing thiocyanate and pyruvate. In addition to its stability for IM injection, it also exerts its effects within 3 minutes [59,60]. Supportive care for cyanide poisoning includes the administration of
oxygen that has been shown to be effective for managing hypoxia, even though the poor cellular uptake and utilization of oxygen found with cyanide toxicity would suggest supplemental oxygen to be of little efficacy. Hyperbaric oxygen may also be beneficial for selected severely ill patients, though this therapy would be difficult to institute in a mass casualty setting [19]. Ventilatory support should be provided when needed. Consideration should be given to the administration of sodium bicarbonate for the treatment of severe lactic acidosis in patients who are unconscious or hemodynamically unstable. Arterial blood gas analysis is used to guide the need for repeat doses of sodium bicarbonate to ensure that a metabolic alkalosis does not develop. In most cases of cyanide poisoning, appropriate supportive care in conjunction with the administration of sodium nitrite and sodium thiosulfate, or hydroxocobalamin before cardiac arrest can result in a complete recovery over a period of several days [55,57,61].

Pulmonary or “Choking” Agents

Pulmonary or “choking” agents cause acute lung injury after inhalation. The acute lung injury produced by these agents typically results in the development of pulmonary edema. Phosgene and chlorine are the two most common chemical agents in this category. Both were used as chemical warfare agents in World War I. Their effects relate, in part, to their water solubility. Highly water-soluble gases like ammonia, hydrogen chloride, and sulfur dioxide affect primarily the eyes and upper airway mucous membranes. Chlorine, a moderately water-soluble gas, affects the upper airway less but also damages the lower airway. Finally, slightly water-soluble gases like phosgene affect primarily the lower airways.

Phosgene is a colorless gas at room temperature, but becomes a volatile liquid on cooling or compression. The gaseous form has an odor of green corn or freshly mown hay. The gas is denser than air and accumulates in low-lying areas. On exposure to water, phosgene hydrolyzes to form carbon dioxide and hydrochloric acid. These hydrolysis products may cause phosgene gas to appear as a white cloud when it comes into contact with water vapor in the air [62].

Initial symptoms of phosgene poisoning are primarily related to inflammatory irritation of the eyes and mucous membranes of the oronasopharynx. The irritation is caused by the hydrochloric acid that is formed when phosgene reacts with tissue water. Initial symptoms occur shortly after exposure and include burning sensation in eyes, conjunctival erythema, increased lacrimation, soreness of the throat and nasal membranes, rhinorrhea, coughing, choking, and tightness in the chest. Nausea, occasional vomiting, and headache have also been reported to occur shortly after phosgene exposure. These may be the only symptoms
that occur following a low-concentration exposure. However, a life-threatening illness, characterized by noncardiogenic pulmonary edema and respiratory failure, can develop after exposure to higher concentrations.

Inhaled phosgene causes the formation of hydrochloric acid in the airways and alveoli that causes direct inflammatory injury to epithelial cells and endothelial cells of pulmonary capillaries. In addition, phosgene causes an acylation reaction with amino, hydroxyl, and sulfhydryl groups on cellular macromolecules, resulting in changes to surfactant structure and function and the development of reactive oxygen and nitrogen species. In addition, phosgene stimulates neuronal Ca\(^{2+}\) channels, resulting in neurotransmitter release, and can induce vasoconstriction \[63\]. It also stimulates the synthesis of lipoxygenase-derived leukotrienes that results in the chemotactic attraction of neutrophils and their accumulation in the lung. In the lung, the damaged alveolar-capillary membrane leads to pulmonary edema. This effect only occurs through direct inhalation.

As noted earlier, inhaled phosgene affects primarily the lower respiratory tract, causing diffuse bronchoalveolar injury, bronchospasm, and noncardiogenic pulmonary edema. Exertion tends to decrease the latency period between phosgene inhalation and the development of pulmonary symptoms, as well as exacerbate pulmonary symptoms once they occur. Phosgene-produced pulmonary edema may begin as early as 2 to 6 hours after inhalation. Although the pulmonary edema may appear to be mild at first, it can become extensive and life threatening. Normal pulmonary lymphatic drainage may be overwhelmed by increasing pulmonary edema that leads to the development of the acute respiratory distress syndrome (ARDS) in some individuals. The onset of ARDS may be delayed for up to 48 hours after phosgene inhalation \[64\].

Chlorine is a greenish-yellow, noncombustible gas at room temperature and normal atmospheric pressure. It is heavier than air and gravitates to low-lying areas if released in the environment. Chlorine has a strong, pungent odor similar to bleach that is usually detectable by smell, even in low concentrations. It is a highly reactive element and, like phosgene, forms hydrochloric acid on contact with water \[62\].

Symptoms of chlorine exposure are similar to those following exposure to phosgene. Initial symptoms occur within minutes after exposure and include burning of the eyes; redness of the conjunctive; increased lacrimation; soreness of the throat and nasal membranes; rhinorrhea; coughing; choking; and tightness in the chest. Burning and blistering of the skin can occur shortly after contact of chlorine with exposed areas \[65\].

Inhalation of chlorine, even in low concentrations, causes immediate coughing and choking that can be severe. The coughing and choking tend
to prevent some of the inhaled chlorine from reaching the peripheral airways and lung tissue. Thus, inhaled chlorine typically affects the upper airway primarily, causing laryngeal edema, laryngospasm, and bronchospasm. Hoarseness and aphony may occur. Dyspnea is the first sign of upper airway involvement, followed by copious secretions, productive cough, and chest tightness. Wheezing typically occurs with bronchospasm. Individuals with a history of asthma or airway hyperactivity may have particularly severe bronchospasm. Severe bronchospasm may cause mediastinal and subcutaneous emphysema secondary to air trapping. Inhalation of high concentrations of chlorine may produce laryngospasm that is severe enough to cause sudden death \[62\]. Chlorine exposure also may result in long-term neurocognitive deficits, including choice reaction time, balance, visual field changes, and verbal recall \[66\].

Noncardiogenic pulmonary edema can occur within 2 to 4 hours following the inhalation of chlorine, especially at high concentrations \[67\]. Frothy sputum and rales may be the first clinical signs of pulmonary edema. Radiographic signs of pulmonary edema typically lag behind the development of clinical symptoms \[68\]. The development of ARDS with hypoxemic respiratory failure may eventually occur. The fluid losses associated with severe pulmonary edema and ARDS can be so profound that hypovolemic shock develops.

Management of individuals exposed to inhaled phosgene and chlorine is essentially supportive with no specific antidote available for either agent. For all cases, the patient must be removed from the contaminated environment and decontaminated as soon as possible by washing the patient with soap and copious amounts of water for 3 to 5 minutes. The eyes should be flushed with normal saline. Exertion should be minimized during transport and hospitalization.

Aggressive bronchodilator therapy with a nebulized $\beta_2$ agonist is the mainstay of therapy for bronchospasm. Nebulized ipratropium may be added if the $\beta_2$ agonist alone is ineffective. Systemic corticosteroids may be useful for the treatment of severe bronchospasm, particularly among individuals who have a history of asthma or airway hyperreactivity. Animal studies have shown that inhaled corticosteroids improve oxygenation and attenuate the development of acute lung injury, especially when given in conjunction with an inhaled bronchodilator \[69\]; this has not, however, been validated for humans. The combination of steroids with nebulized sodium bicarbonate was efficacious in the
treatment of 25 soldiers who were exposed to acute chlorine gas inhalation [70]. Thus, although systemic corticosteroids are recommended for life-threatening situations, there is no definitive clinical evidence for their efficacy in reducing the severity of acute lung injury or pulmonary edema.

Bacterial superinfection of the airways can lead to the development of severe tracheobronchitis and pneumonia 3 to 5 days after toxic irritant exposure. The presence of persistent fever, elevated white blood, or the production of thick, purulent sputum should prompt the physician to obtain cultures of sputum, blood, and any pleural fluid that is evident on chest radiograph. Empiric antibiotics should be given in accordance with the guidelines for intensive care unit patients with community-acquired pneumonia [62].

Intubation and mechanical ventilation may be required for severe bronchospasm, laryngospasm, and pulmonary edema. They are usually required for the management of ARDS and respiratory failure. Given the rapidity with which these problems can develop, preparations for intubation and mechanical ventilation should take place during the latency period, before serious respiratory problems develop. Nasotracheal intubation should not be performed because of nasal inflammation. Orotracheal intubation with visualization of the airways is the recommended technique. During mechanical ventilation, an appropriate amount of positive end-expiratory pressure, typically in the range of 5 to 10 cm H$_2$O, and other rescue therapies may be needed to improve oxygenation for patients with pulmonary edema or ARDS (see Chapters 163 and 166). Using animal models, protective ventilation strategies with 6 mL/kg tidal volumes improve oxygenation, are thought to decrease shunt fraction, and improve mortality [71].

Careful attention must be given to fluid balance and the administration of intravenous fluids in patients with pulmonary edema and ARDS. Vasopressors may be required for the treatment of hypovolemic shock. Both ibuprofen and acetylcysteine aerosol have demonstrated some efficacy for preventing phosgene-induced lung injury of animal models, although there are no human clinical trials regarding their use [72,73].

Pulmonary edema that appears within 4 hours after phosgene or chlorine exposure is a poor prognostic sign. Some individuals may develop the reactive airways dysfunction syndrome (RADS) following phosgene or chlorine inhalation [74,75]. This disorder is characterized by chronic, nonspecific airway hyperreactivity that persists after the patient has recovered from the effects of an acute exposure. Patients who develop RADS should receive prompt treatment with oral prednisone (40 to 80 mg daily for 10 to 15 days) followed by treatment with a high dose of an inhaled corticosteroid, such as beclomethasone (2,000 μg per day). RADS patients should be followed closely with serial methacholine bronchial
challenge testing, and the dose of oral corticosteroid should be tapered in accordance with improvements of airway hyperresponsiveness. It may take years for some individuals with RADS to show significant improvement in airway hyperresponsiveness [76]. However, most individuals who survive phosgene or chlorine exposure will recover completely with no long-term effects [62].

With increased understanding of the mechanisms of cellular damage, newer therapies are being investigated. These may include neuromodulators that interrupt signalling pathways, phosphodiesterase inhibitors, angiotensin, and endothelin [64]. Approaches to upregulate repair to damaged alveolar membranes with keratinocyte growth factor, epithelial growth factor, and basic fibroblast growth factor are being explored in the management of ARDS that results from inhalation [77]. Several stem cell lines could also prove useful in the future in mitigating the long-term effects of inhalation injury such as asthma, COPD, pulmonary fibrosis, and lung cancer [78].

Nonlethal Incapacitating Agents

Chemical agents that cause temporary incapacitation are commonly classified as nonlethal agents. These chemical agents, although potentially lethal in high concentrations, are typically employed at doses that cause temporary injury. They are commonly used to incapacitate unruly individuals or groups in riot control situations. However, they could also be used by terrorists during an attack. In this regard, they could be used alone, they could be used prior to an attack with conventional weapons, or they could be used in conjunction with other chemical, biologic, or radiologic agents of mass destruction.

The most common incapacitating agent is BZ (QNB; 3-quinuclidinyl benzilate), a competitive inhibitor of acetylcholine at postsynaptic and postjunctional muscarinic receptors. BZ is a stable, odorless, persistent crystalline solid. It is usually dispersed as a fine solid powder, although it can be dissolved in a liquid substrate and dispersed as a liquid aerosol. Both the powder and aerosolized forms can be readily ingested or inhaled. Ingestion and inhalation of BZ particles that are 1 μm in size result in bioavailabilities that are approximately 80% and 50% of a parenteral dose, respectively [79].

The clinical effects of BZ are similar to those of atropine, although BZ is approximately 25 times more potent and has a much longer duration of action. Symptoms of exposure include mydriasis; blurred vision; dry mouth; indistinct speech; dry skin; increased deep tendon reflexes; poor coordination; decreased level of concentration; illusions; and short-term memory deficits. The most prominent central nervous system effects of BZ are related to the so-called “anticholinergic delirium.” The delirium
typically occurs after high-dose exposure and has been described as a “walking dream,” a syndrome characterized by periods of staring, unintelligible muttering, occasional shouting, and bizarre hallucinations. The degree of delirium can fluctuate frequently from minute to minute, with periods of lucidity and appropriate responses interspersed among periods of severely altered mental status [5,79].

The intensity and duration of anticholinergic symptoms associated with BZ exposure are dose-dependent, with higher doses causing more severe symptoms and a longer durations of effects. Incapacitating symptoms typically appear within 1 hour after exposure, peak at approximately 8 hours after exposure, and subside gradually during the next 48 to 72 hours. All individuals exposed to BZ should be decontaminated by washing the entire body with soap and water. Medical therapy is mostly supportive, to include control of the patient for the prevention of accidents, removal of dangerous objects from the patient’s environment to prevent self-inflicted harm during delirium, moist swabs or hard candy for dryness of the mouth, keeping the room temperature at 75°F or below to prevent the development of hyperthermia, and the use of topical antibiotics and sterile dressings for abrasions of dry, parched skin. Severe signs and symptoms of BZ exposure can be treated with physostigmine which temporarily raises acetylcholine concentrations by binding reversibly to anticholinesterase on postsynaptic or postjunctional membranes. Physostigmine can be administered either intravenously or intramuscularly. The recommended intravenous dose is 0.5 to 1.0 mg by slow infusion at a rate over 2 to 5 minutes for adults and 0.01 mg/kg for children. The patient should be evaluated every hour for improvement in signs and symptoms, with physostigmine readministered periodically at a dose and time interval that is titrated to the severity of clinical signs. Physostigmine can cause a precipitous decrease in heart rate and patients should be carefully monitored during its administration. It should not be administered to any patient with cardiopulmonary instability, hypoxemia, electrolyte imbalance, or acid–base disturbances that predispose to cardiac dysrhythmias and seizures. An intravenous test dose of 1 mg should be administered to adults if the diagnosis of BZ exposure is in doubt. If slight improvement is noted and there are no adverse effects within 1 hour, the full dose can be given [5,79].

Riot control agents are intended to produce unpleasant but nonpersistent medical effects. They are sometimes referred to as irritants. The two riot control agents most commonly used are 2-chloro-1-phenylethanone (CN or MACE; MACE Security International,
Cleveland, OH) and 2-chlorobenzalmalononitrile (CS or tear gas). Another product used for riot control or security is oleoresin capsaicin (OC or pepper spray). All riot control agents cause significant irritation to the eyes, upper airways, and skin. In addition to burning of the eyes and increased lacrimation, exposed individuals may experience temporary blepharospasm with transient blindness. Upper airway symptoms include rhinorrhea, sneezing, salivation, and tightness of the chest. Exposed individuals with preexisting reactive airway disease may develop bronchospasm, which can progress to respiratory failure [80]. Because riot control agents are dispersed as a solid powder, decontamination consists of getting the victims out of any confined spaces and into fresh air, removing their clothing, and irrigating their eyes and mucous membranes with normal saline. Treatment is nonspecific and supportive. The latency period for most symptoms is hours to several weeks, and most resolve in 15 to 30 minutes though they can last several days; exacerbation of reactive airway disease may last many months. Episodes of acute bronchospasm in susceptible individuals should be treated with a short-acting $\beta_2$ agonist administered by nebulizer [81,82]. Providers must be aware that exposure to agents in a patient’s oropharynx may produce symptoms in the provider during endotracheal or nasogastric intubations.

Finally, a variety of other readily available compounds can be aerosolized and need to be considered as potential incapacitating agents. Nausea-producing agents such as diphenylaminearsine (DM or “adamsite”) can produce incapacitating gastrointestinal symptoms. Psychedelic drugs, such as 3,4-methylenedioxymethamphetamine and phencyclidine, are easily obtained and could be used as aerosolized incapacitating agents. In October 2002, carfentanil, a potent aerosolized derivative of fentanyl, was probably employed in combination with halothane in an attempt by Russian authorities to release more than 800 hostages held by terrorists in Moscow’s Dubrovka Theater. Unfortunately, 127 hostages in the theater died, and more than 650 were hospitalized after being exposed to the chemicals that were used in the rescue attempt [83]. This is a good example of how readily available pharmaceutical agents can be used to incapacitate, or even kill, a large number of individuals.
SUMMARY

Chemical agents pose a significant threat to populations throughout the world, whether accidentally released from an industrial or transportation accident, or released intentionally as part of a crime or terrorist event. Regardless of the cause of release, they have the potential to produce a large number of casualties in a short period of time. However, the terminology *weapons of mass destruction* does not entirely reflect the impact that a terrorist attack with such agents could have on the general population. Even a relatively small number of casualties from a terrorist attack would be likely to cause significant psychologic trauma, resulting in anxiety and behavioral changes among large numbers of “worried well.” Such psychologic trauma could significantly disrupt healthy business and community activities for a long period of time. Instilling widespread fear and anxiety in the general population is a primary goal of terrorism and, unfortunately, the use of chemical agents is an efficient method of achieving that goal.

Critical care providers must be prepared to deal with the recognition, decontamination, transport, medical treatment, and psychologic trauma of casualties resulting from chemical agents. They must also be prepared to protect themselves and colleagues from contamination with chemical agents during the course of patient care. Training in the medical management of chemical agent casualties and planning for mass casualty situations are essential to ensure that the best possible care is provided to the victims of a chemical exposure or chemical attack.

INTRODUCTION

The objective of this chapter is to become familiar with the medical consequences and casualty management considerations following a radiologic or nuclear incident.
TYPES OF RADIATION EMERGENCIES

Radiation emergencies may result from a number of accidental or deliberate events. Radiologic dispersion devices (RDDs), or “dirty bombs,” are devices that cause intentional dissemination of radioactive material without a nuclear detonation. The radioactive material is released and dispersed by the detonation of the high-explosive charge. It is important to note that dirty bombs are not nuclear weapons and are not weapons of mass destruction. “Dirty bombs” may cause internal radiation exposure through the inhalation or ingestion of contaminated materials in the food chain and external radiation exposure through surface contamination [1,2]. The adverse health effects depend on the type and amount of explosive and radioactive material used and atmospheric conditions at the time of detonation. Most injuries from a dirty bomb will come from the blast effects of the conventional explosion [1,2]. Acute and delayed health effects caused by radiation are unlikely. Delayed health effects, such as the development of cancers, following an RDD attack, are related to the radiation exposure dose and to the amount of internal radiation that results from the inhalation, ingestion, and absorption of radioactive material through the skin or open wounds. An RDD can cause significant impact on the short- and long-term social, psychologic health of the masses [2,3].

Radiologic exposure devices (REDs) are radioactive nuclear materials that are covertly placed with the intention of exposing victims to harmful radiation without their knowledge [1]. The dangers of an RED depend upon the type and amount of radioactive material used, the duration of exposure, the proximity of the source, and the part of the body exposed. Unexplained burns, cytopenias, or the development of other symptoms consistent with the acute radiation syndrome (ARS) can alert providers to the possible presence of an RDD. Some radioactive materials of concern used as RDDs are the americium-241, californium-252, cobalt-60, caesium-137, iridium-192, and strontium-90 [2].

A nuclear explosion results from nuclear fission or from thermonuclear fusion, during which a tremendous amount of energy is suddenly released in the form of heat, blast, and radiation. Human injury is caused by exposure to a combination of these three forms of energy following a nuclear detonation. The energy released from a nuclear explosion can be very intense and lead to a life-threatening ARS, radiation burns, thermal burns, and blast injuries. Radiation exposure can result in the development of various types of cancer and leukemia over a period of many years if an individual survives the initial short-term effects of a nuclear explosion. These radiation effects on the human body can be
classified into two categories: deterministic effects and stochastic effects. Deterministic effects are dose-dependent, and their effects are absent below certain threshold; they are responsible for organ damage and infertility. Stochastic effects are dose-independent, and the effects are not proportional to the dose of radiation; they are responsible for cancer and genetic damage [3].

Nuclear power plant accidents are another potential source of radiation exposure. The Chernobyl nuclear accident, Three Mile Island event, and the recent Fukushima Daiichi Nuclear Power Plant accident are the most notable examples in recent times.

Nuclear power plant accidents differ from nuclear weapon detonations, in that nuclear weapons use enriched uranium or plutonium in higher concentrations and configurations than those used by power plants. Reactor accidents can release various radioisotopes that have different effects on humans. Radioisotopes with very short or very long half-lives and gaseous forms that are released in small quantities may not produce significant internal or external radiation injuries, whereas iodine-131 isotope can contaminate the environment with long-term effects [4]. The accident at the Fukushima Daiichi Nuclear Power Plant in Japan in March 2011 resulted in the environmental release of radioactive substances, predominantly iodine-131, caesium-134, xenon-133, and strontium-90. Most of the radioactivity was released during a period of approximately 40 days with traces of radioisotopes detected globally. No acute radiation injuries were reported from the Fukushima Daiichi Nuclear Power Plant disaster. Based on the published data, the maximum estimated lifetime cancer mortality and morbidity from Fukushima Daiichi Nuclear Power Plant, however, are increased for the exposed population [4–6].

Accidental exposure during the transportation, industrial use, or medical use of radioactive materials has also led to a wide range of radiation injuries.

ARS is a deterministic effect that may develop among radiation-exposed individuals following a radiologic incident. The pathophysiology behind the cell damage from ionizing radiation is owing to the radiosensitivity of certain cell lines. ARS consists of a continuum of complex and unique medical subsyndromes that involve the hematopoietic, gastrointestinal, and central nervous systems in a dose-related fashion. Patients who develop any of the acute radiation subsyndromes require prompt assessment and critical care management to minimize loss of life. The ARS and its associated subsyndromes are discussed in detail later in the chapter.
**BASIC RADIATION PHYSICS**

Radiation is defined as energy that is transmitted through space. The transmitted energy may be in the form of high-speed particles or electromagnetic waves. There are two general types of radiation: ionizing radiation and nonionizing radiation. Ionizing radiation has enough energy to remove tightly bound electrons from their orbits and cause an atom to become charged. Nonionizing radiation does not have enough energy to remove electrons from their orbits. Ionizing radiation is more harmful to humans than nonionizing radiation and is the type of radiation that would be expected to be released by a radiologic or nuclear attack.

Ionizing radiation can take four forms: alpha, beta, gamma, and neutron. Alpha radiation consists of the emission of a helium nucleus from a parent nucleus, such as uranium-235; it is a particle that has an atomic mass of four and a charge of plus one. Beta radiation is the emission of a small negatively charged particle from a parent nucleus, such as potassium-40. Beta particles have a mass that is almost undetectable and a charge of minus one, similar to that of an electron. Gamma radiation is the emission of high-energy electromagnetic waves from a parent nucleus, such as cobalt-60. Gamma rays have no mass and no charge and frequently accompany the emission of alpha or beta particles. Neutrons are very high-energy particles emitted from parent nuclei, such as uranium-235 and plutonium-239 during a nuclear chain reaction. Nuclear chain reactions can be controlled, such as the kind found in a nuclear reactor, or they can be uncontrolled, such as the type that causes a nuclear explosion. Neutrons can induce severe damage to human cells and tissues [8,9].

Each specific type of ionizing radiation has a different penetrating distance on inert material and human tissues. Alpha particles will not penetrate paper or intact human skin. However, if alpha particles are ingested, inhaled, or internalized through a break in the skin, they can do a tremendous amount of internal damage to human cells and tissues [8,9].

Beta radiation will penetrate paper, thin layers of skin, and the conjunctiva of the eye but will not penetrate thin layers of plastic or aluminum foil. Beta particles travel relatively short distances and will be stopped by most clothing. As with alpha particles, beta radiation can
induce severe damage to human tissues when inhaled or ingested [8,9].

Gamma rays can travel significant distances and are a highly penetrating type of ionizing radiation. They readily penetrate skin and clothing. Gamma radiation can cause considerable damage to human cells and tissues after penetration. Several inches of lead or several feet of concrete are required to stop gamma rays [8,9].

Neutrons are high-energy nuclear particles that have no charge. Neutron radiation easily penetrates skin and clothing and can cause significant damage to internal tissues and organs. Neutrons primarily cause biologic damage by colliding with other particles. They transfer the most energy when they collide with particles that are about the same size, especially protons. These high-energy, subatomic collisions result in the dislodgement of both protons and tightly bound electrons from atoms that are bombarded by neutrons, with ionization of atoms in surrounding cells and tissues. Neutron radiation is extremely harmful to humans. It cannot be stopped by plastic, glass, or lead; it can only be stopped by several feet of concrete [8,9].

Ionizing radiation causes damages to human cells and tissues through two biologic mechanisms: (1) direct high-energy damage to deoxyribonucleic acid (DNA) molecules and (2) the generation of free radicals, which secondarily damage DNA molecules by superoxide radicals generated from ionized water. The fate of irradiated human cells is dependent on the dose of radiation received. Low-dose exposures are characterized by DNA and cellular repair. Moderate-dose exposures are characterized by permanently damaged DNA and significantly altered cells, which may be eliminated by apoptosis or may be reproduced abnormally and eventually leading to the development of a cancer. High-dose radiation exposures typically result in cell death, which causes several serious ARSs that can result in the death of the organism [10,11].

Human radiation exposure can be categorized as either external or internal. External exposure may occur in either whole body or partial body depending on the surface area exposed to radiation. Internal exposure may occur from the inhalation, ingestion, or transdermal penetration of radioactive material. Combined radiation injuries may also occur among cases where radiation exposure and trauma occur concurrently. During combined radiation injuries, radioactive material can be introduced through open wounds.
There are two units of radiation doses that physicians must be familiar with: the rad and the gray (Gy). It is not essential for clinicians to understand the physics that underlie the determination of these doses, but it is important for them to know that these are the units that are used to express the amount of radiation that is absorbed by human tissues. The Rad is the traditional unit of radiation-absorbed dose. The Gy is the newer Standard International unit of radiation exposure. One Gy (100 centigrays or 100 cGy) is equal to 100 rads [12].

Radiation doses can be measured by using several techniques. Radiation detection, indication, and computation (RADIAC) devices such as the Geiger–Muller counters can help by detecting radiation exposures at a given time compared with dosimeters that measure the total dose accumulated. There are many different types of radiac meters, each of which may be more sensitive to specific types of radiation, such as alpha, gamma, or neutrons, than to other types of radiation. It is important, therefore, to know both the capabilities and limitations of any radiac meter that one uses to determine radiation doses. Useful clinical indicators of whole body radiation dose are time to vomiting and total lymphocyte count at 24 to 48 hours postexposure [13]. The dose range in Gy and the estimated lethality associated with each dose range are illustrated in Table 129.1.

Chromosomal aberrations and translocations in lymphocytes can also provide a useful estimate of both the type of radiation that one has been exposed to as well as the radiation dose. One such method called the dicentric chromosomal assay is considered the gold standard in the estimation of absorbed dose of the exposed radiation and is very sensitive to ionizing radiation [14,15]. These methods require considerable expertise in fluorescent in situ hybridization techniques as well as expertise in the interpretation of the chromosomal abnormalities.
OVERVIEW OF RADIATION CASUALTIES

Radiation casualties are of two general types: an ARS and delayed illnesses that may occur many years after radiation exposure. ARS is a life-threatening condition consisting of a continuum of dose-related subsyndromes that occur shortly after a high-dose radiation exposure, such as those that occur following the detonation of a nuclear weapon. Delayed illnesses include malignancies such as leukemia, lymphoma, and various solid tumors; late organ damage includes thyroid dysfunction; fibrotic changes of organs including the skin, blood vessels, and lymphatics; pregnancy loss; and genetic abnormalities of progeny. Delayed illness caused by radiation is likely from exposure that is lower than that is needed for the ARS. In general, the higher the radiation dose, the more severe the acute effects of radiation exposure, the greater the probability of delayed illnesses, and the higher the mortality rate [3,7].

In considering the human dose–response to radiation exposure, the measurement LD (lethal dose)\textsubscript{50/60} is commonly used. The LD\textsubscript{50/60} is the radiation dose that causes a 50% mortality rate in an exposed population within 60 days following exposure. For whole body radiation exposure, the LD\textsubscript{50/60}, with no treatment, is 3 to 4 Gy. Therefore, 50% of a population that receives a radiation dose of 3 to 4 Gy will die within 60 days unless they receive treatment. With appropriate treatment including antibiotics and transfusions following radiation exposure, the LD\textsubscript{50/60} can be calculated as 4 to 5 Gy [7].
ACUTE RADIATION SYNDROME AND SUBSYNDROMES

ARS is a continuum of dose-related organ system subsyndromes that develop after an acute radiation exposure of greater than 1 Gy. There are three main subsyndromes that occur: the hematopoietic subsyndrome, the gastrointestinal subsyndrome, and the central nervous system subsyndrome. Each of these subsyndromes occurs in a dose-dependent manner. The hematopoietic subsyndrome occurs with radiation exposures greater than 1 Gy. The gastrointestinal subsyndrome occurs in addition to the hematopoietic subsyndrome at radiation exposures greater than 6 Gy. The central nervous system subsyndrome occurs in addition to the hematopoietic and gastrointestinal subsyndromes at radiation exposures greater than or equal to 20 Gy.

All acute radiation subsyndromes begin with a prodromal phase of nausea, vomiting, diarrhea, and fatigue that last for minutes to days. The higher the radiation dose, the more rapid the onset and the more severe the symptoms of the prodromal phase. After this phase, the patient enters a latent phase, in which he or she appears to recover and is often asymptomatic. The latent phase may last for several days to 1 month, with the period inversely proportional to the radiation exposure dose; that is, the higher the dose, the shorter this phase. After the asymptomatic latent phase, the patient enters the manifest illness phase. This phase of acute radiation illness lasts from several days to several weeks and is characterized by the manifestation of the hematopoietic, gastrointestinal, and central nervous system subsyndromes, according to the exposure dose that the patient received [16].

Some individuals may develop radiation-associated multiple organ dysfunction syndromes (MODSs) in association with the organ-specific clinical syndromes mentioned above. Multiple organ system dysfunction typically occurs in the manifest illness phase but may also occur early after a sublethal radiation exposure. Many patients with hematopoietic, gastrointestinal, central nervous system and MODSs will require management in an intensive care unit [17].

The Hematopoietic Subsyndrome

The hematopoietic subsyndrome typically occurs with a radiation dose of greater than 1 Gy. It is characterized by bone marrow suppression resulting from the radiation-induced destruction of hematopoietic stem cells within the bone marrow. Hematopoietic stem cell destruction results
in a progressive decrease in lymphocytes, neutrophils, and platelets in the peripheral blood. Both the magnitude and the time course of the pancytopenia are related to the radiation dose. In general, the higher the radiation dose, the more profound and the quicker the pancytopenia occurs [7].

Lymphocytic stem cells are exquisitely sensitive to radiation, and circulating lymphocytes decrease rapidly following radiation exposure (see Table 129.1). Erythrocytic stem cells, on the other hand, seem to be more resistant to radiation than lymphocytic, neutrophilic, and thrombocytic stem cells. Therefore, the red blood cell count and hemoglobin concentration typically do not decrease to the same extent as lymphocytes, neutrophils, or platelets following radiation exposure [13].

As shown in Table 129.1, the hematologic effects of acute radiation exposure are dependent on the radiation dose. A radiation exposure of 3 Gy or more results in more significant hematologic effects than a radiation exposure of 1 Gy. Lymphocytes will decrease very rapidly following a radiation exposure of 3 Gy, and they will stay low for a relatively long period. Typically, it takes approximately 90 days before lymphocytes begin to recover from a 3-Gy radiation exposure. Neutrophils, after an initial period of intravascular demargination, will also begin to decline fairly rapidly following a 3-Gy exposure. Neutrophils do not fall as rapidly as lymphocytes, but between 3 and 5 days following exposure, such patients will be significantly neutropenic. Platelets also decrease steadily following a 3-Gy exposure, and patients will become significantly thrombocytopenic at 2 to 3 weeks. Both platelets and neutrophils will reach a nadir, with values close to zero, at approximately 30 days following a 3-Gy exposure. Platelets and neutrophils then recover gradually during the next 30 to 40 days. Lymphocytes remain low for a longer period, however, and typically do not begin to recover for at least 90 days following a 3-Gy exposure. Thus, there is a period of about a month following a 3-Gy exposure when patients will be significantly lymphopenic, neutropenic, and thrombocytopenic. Such patients are susceptible to developing serious infections and serious bleeding problems during that time [13,18].

The Gastrointestinal Subsyndrome

The gastrointestinal subsyndrome typically occurs following an acute radiation dose of greater than 6 Gy. It develops as a result of radiation damage to intestinal epithelial cells. The loss of epithelial cells results in denudation of the intestinal mucosa. Following the asymptomatic latent phase, patients will develop a manifest illness phase characterized by fever, vomiting, and severe diarrhea. Malabsorption, severe fluid losses, and severe electrolyte derangements will follow. Most patients will have
severe pancytopenia as a result of a coexisting hematopoietic subsyndrome. Mucosal translocation of pathogens, sepsis, and opportunistic infections commonly occur. The resulting sepsis can be very severe and typically involves enteric organisms that migrate into the systemic circulation through damaged and denuded gastrointestinal mucosa. Approximately 10 days after the onset of the manifest illness phase, these patients typically develop fulminant bloody diarrhea that usually results in shock and subsequent death [7,16,19].

The Central Nervous System Subsyndrome

The central nervous system subsyndrome is seen with radiation doses greater than or equal to 20 Gy, although cognitive dysfunction can be seen with radiation doses greater than 10 Gy. The latent period is very short, lasting from several hours to 3 days. Following the asymptomatic latent period, patients typically develop nausea, vomiting, diarrhea, and confusion. Microvascular leaks in the cerebral circulation result in cerebral edema. Elevated intracranial pressure and cerebral anoxia may develop rapidly. Mental status changes develop early in the manifest illness phase, and the patient eventually becomes comatose. Seizures and burning dysesthesia may occur. Patients typically die within hours to several days after onset of the manifest illness phase of the central nervous system subsyndrome [1,7,20,21].

Multiple Organ Dysfunction Syndrome

Some patients may develop multiple organ system dysfunction following exposure to ionizing radiation. This syndrome was first reported following the September 30, 1999, Tokaimura nuclear accident [22]. Radiation-induced multiorgan involvement or multiple organ failure (MOF) is defined as a progressive dysfunction of greater than two organs over time [17]. They are not limited to the four-organ system included in the ARS. Prominent organs involved are the lungs, liver, kidney, and the cardiovascular system. There is no well-defined dose–effect relationship that has been associated with its development. The pathophysiology behind the development of MODSs and MOF is still not well construed, though it may be a consequence of a “two-hit phenomenon” where the initial insult is considered a consequence of irradiation-induced radiolysis of cells, inflammation, increased prooxidative metabolic reactions, injury to hematopoietic, lymphoid tissues, intestinal mucosa, or vascular endothelium. The injury to gut mucosa leads to bacterial
translocation and spread of the bacterial pathogens and proinflammatory agents through the vascular system leading to septic inflammatory and metabolic responses [7,17,23–25]. Such patients will require prompt supportive care and treatment in an intensive care unit to maximize their potential for survival [17].

**Prognosis**

The prognosis of patients who develop acute radiation subsyndromes depends on the radiation dose to which they were acutely exposed and whether they have concomitant trauma. Nearly all patients exposed to 1 to 2 Gy will survive. Survival is possible for patients exposed to doses of 2 to 6 Gy, but many of these patients will require prompt treatment and intensive care to survive. Survival is possible, but improbable, for patients exposed to doses of 6 to 8 Gy. In addition to prolonged critical care support, these patients may require stem cell transplantation. Even with the most aggressive treatment, survival is extremely rare following exposure doses above 10 Gy and has not been reported following doses greater than 20 Gy [29].

**Management**

Initial medical care for all casualties of a radiologic event will include triage, resuscitation and first aid, medical stabilization, decontamination, and treatment of minor injuries. All patients with significant acute radiation exposure will receive supportive care. This consists of fluids and electrolyte replacement, antiemetic agents to manage vomiting, antidiarrheal agents to manage diarrhea, proton pump inhibitors for gastrointestinal ulcer prophylaxis, pain management, psychologic support, and palliative care when death is imminent. The main objective of management for ARS is to prevent neutropenia that can lead to sepsis. Care should be taken to prevent the development of infection or bleeding by avoiding unnecessary instrumentation particularly involving the gastrointestinal tract.

Hematopoietic growth factors or colony-stimulating factors (CSFs) are endogenous glycoproteins that stimulate the bone marrow stem cells to mature into blood cell types. The basis to use CSFs for patients exposed to radiation is derived from studies that followed cancer patients, among a small cohort of radiation-exposed victims, and several prospective trials of canines and nonhuman primates exposed to radiation. Granulocyte CSF (G-CSF), although not approved by US Food and Drug Administration for hematopoietic ARS, is used off-label for the management of ARS [7]. Growth factor therapies should be prophylactically initiated for early recovery of hematopoiesis preferably within 2 to 4 days for those exposed to a significant level of whole body
radiation particularly greater than 3 Gy. Multiple studies have demonstrated the role of G-CSFs for reducing the duration of radiation-induced neutropenia, enhancing neutrophil recovery, and providing survival benefits. For radiologic events involving <100 casualties, growth factor therapy can be considered for patients exposed to radiation of 2 to 6 Gy when there is no significant burn or trauma. If the exposure is between 2 and 6 Gy and the patients have burns or trauma, growth factor therapy is still warranted. The therapy is usually continued until the absolute neutrophil count is more than 1,000 per mm$^3$ [29]. If the exposure is greater than 6 Gy without trauma, it is prudent to consider stem cell transplant [30].

Various types of G-CSFs can be given: G-CSF (filgrastim), pegylated G-CSF (pegfilgrastim), or GM-CSF (sargramostim) and recently added tbo-filgrastim. These are all commercially available preparations and used for the management of hematopoietic subsyndromes. The recommended doses of the various cytokines for the treatment of acute radiation subsyndromes in adults are summarized in Table 129.2 [29]. The role of antibiotics for the management of ARS depends on the patient’s absorbed radiation dose, absolute neutrophil counts, and potential sources of infection. No antibiotic prophylaxis is recommended for patients who received radiation <2 Gy. For patients exposed to a moderate amount of radiation ranging from 2 to 6 Gy, antibacterials are initiated for febrile neutropenia along with possible antiviral and antifungal prophylaxis. Antibacterials are considered when focal infections are identified in patients who are afebrile, but neutropenic. For severe cases of radiation exposure to 5 to 10 Gy, early antiviral, antifungal, and antibiotics are started for anticipated significant immune suppression fluoroquinolones with or without amoxicillin/penicillin for streptococcal coverage, which is the preferred prophylactic regimen in these patients. The preferred antifungal and antiviral are fluconazole and acyclovir, respectively. Prophylactic antibacterials are continued until treatment failure or development of neutropenic fever or when the absolute neutrophil count is greater than 500/mm$^3$. In such cases, fluoroquinolones are discontinued, and antibacterials with antipseudomalonal coverage are introduced. Gram-positive coverage is initiated as per the hospital sensitivity biogram. The Infectious Diseases Society of America guidelines for neutropenic fever management are recommended for febrile neutropenic patients [13,30].

</tbody>
</table>

Blood transfusions are indicated for patients with an acute radiation subsyndrome who have severe bone marrow damage or who require concurrent trauma resuscitation. Transfusion requirements do not rise until 2 to 4 weeks after exposure unless the patient needs replacement of blood products for concurrent trauma. The purpose of blood transfusions for such patients is to provide erythrocytes for the improvement of oxygen-carrying capacity, blood volume to improve hemodynamic parameters, and platelets to help prevent bleeding. All cellular products in the blood to be transfused should be leukoreduced and irradiated to 25 Gy to prevent transfusion-related graft-versus-host reaction among immunocompromised patients [30].

Stem cell transplantation should be considered for certain patients with acute radiation illness. Allogeneic stem cell transplantation is indicated for individuals who have a radiation exposure dose of 7 to 10 Gy [30].
ACUTE RADIATION ILLNESS AND TRAUMA

The blast from a nuclear detonation can produce significant trauma along with the associated radiation injuries. The injuries from these blasts arise from the high pressures and wind, flash from the nuclear detonation, thermal pulses, and secondary fires.

The management of combined radiation injuries and trauma presents special challenges to the physician. There is a significant increase in mortality among patients who have this combination of an ARS and an injury. These patients require prompt medical and surgical care to survive. They should receive the treatments for ARSs, as described earlier in the subsyndrome sections. They are also very susceptible to operative and postoperative infections as a result of decreased neutrophil and lymphocyte counts and require 2 to 3 months for their bone marrow to recover from the acute radiation exposure. For a patient with a combination of an ARS and trauma requiring surgery, the surgery must be performed 36 to 48 hours after the initial radiation exposure because of high risk of radiation-induced cell damage and resultant poor healing. If surgery is not performed in this “window of opportunity” following acute radiation exposure, it may have to be postponed for up to 2 months until full hematopoietic recovery happens [13,30].
ACUTE RADIATION DERMATITIS

An acute radiation dermatitis may occur in conjunction with acute radiation illness. The symptoms and signs of acute radiation dermatitis typically appear several days after an acute radiation exposure. Although acute radiation dermatitis is essentially a radiation burn, it is different from the thermal burns that may occur immediately after exposure of the skin to a nuclear explosion. The Centers for Disease Control and Prevention has classified cutaneous radiation injury into three grades based on the extent of exposure to radiation. Exposure of the skin to radiation doses greater than 2 Gy causes epilation and typically occurs 14 to 21 days postexposure. On exposure to 6 Gy, erythema develops secondary to arteriolar constriction with capillary dilation and local edema. At 10 to 15 Gy radiation, dry desquamation occurs because of the involvement of the germinal layer of the epidermis. This leads to thinning of the epidermis and desquamation of skin. Wet desquamation occurs when the skin is exposed to 10 to 25 Gy of radiation to the development of intracellular edema progressing to macroscopic bullae. For patients exposed to greater than 25 Gy of radiation, radionecrosis and ulceration of skin occur. The two main approaches for managing acute radiation skin injury are operative and nonoperative treatment. Nonoperative treatments include infection control and pain and wound care management. Operative treatments include superficial debridement to prevent septic foci and skin grafting when this is required. Topical antibiotics with dressings are used for blistering phase, and silver sulfadiazine cream with nonadherent dressings is preferred for wet desquamation. Systemic antibiotics are used for selected cases. Radiation-induced skin ulcers, nonhealing wounds, and skin ulcers with intractable pain need surgical interventions. Tissue grafts may be required at necrotic sites involving large dermal area [13,30].
INTERNAL CONTAMINATION

Internal contamination is contamination within the body and can occur by the inhalation, ingestion, injection, or the transdermal penetration of radioactive materials. Contamination enters via a variety of portals, such as the nose, the mouth, and a wound, or with a large enough dose, by the penetration of gamma rays or neutrons directly through intact skin. Internal organs commonly affected by internal radiation contamination are the thyroid, the lung, the liver, adipose tissue, and bone. Leukemia and various types of cancers can develop in these organs many years after an acute radiation exposure with internal contamination.

Assessment of Potential Internal Radiation Contamination

The patient history is crucial to determining whether they may have experienced internal contamination. Any history that suggests that a patient may have inhaled, ingested, or internalized radioactive material through open wounds should prompt further evaluation for internal contamination. This assessment should attempt to identify both the radiation dose received and, if possible, the specific isotopes that caused the internal contamination. An initial survey of the patient should be performed with a radia meter, especially around the mouth, nose, and wounds, to give some idea of the extent of any possible internal exposure. The diction of radioactive isotopes on nasal swabs can be very helpful to determine whether a patient has been exposed internally. If it is suspected that a person has inhaled a significant amount of radioactive material, bronchoalveolar lavage can be considered for identifying inhaled radioactive isotopes as well as for removing residual contaminated materials from the lungs. Bronchoalveolar lavage has been shown to be effective for removing inhaled material contaminated with radioactive isotopes from the lungs of animals. The collection and analysis of stool and urine samples can be very helpful for determining both the type and the amount of internal radiation that an individual might have received. Chest and whole body radiation counts can also be helpful for determining the extent of internal radiation contamination. Unfortunately, however, most medical institutions do not have the capability to do either chest or whole body radiation counts. The analysis of nasal swabs, stool samples, and urine samples is the most practical method for determining the type and extent of internal radiation contamination that is used by hospital-based physicians [13].
Treatment of Internal Radiation Contamination

Patients who have experienced internal radiation contamination should be promptly treated to reduce the absorbed radiation dose and prevent the development of future health problems. The goals of treatment are to reduce absorption and enhance elimination of the internal radionuclide contaminant. There are three main categories of agents that are used to treat internal radiation contamination: purgative agents, blocking agents, and chelation agents. Specific agents are used to treat internal contamination by specific radioactive isotopes. Such treatment is most effective when given as soon as possible after the radiation exposure. Gastric lavage can be used to empty the stomach completely after the potential ingestion of radionuclides. When promptly performed, it can decrease the concentration of radionuclides in the gastrointestinal tract. This could result in a decrease in the absorbed radiation dose. In deciding whether to treat a patient for internal radiation contamination, the physician should treat potentially exposed individuals empirically based on the information that is available [1,13,26,30].

Purgative Agents

Purgative agents help to remove radionuclides from the gastrointestinal tract. The most common purgatives are laxatives and enemas, which are helpful for reducing the residence time of radionuclides in the colon. Prussian blue (ferric ferrocyanide) is an ion exchange resin that binds cesium-137 in the gastrointestinal tract and facilitates its secretion. Patients who have experienced internal cesium-137 should be treated with oral Prussian blue (3 g, three times daily) for at least 3 weeks. Aluminum phosphate binds strontium-90 in the gastrointestinal tract. A single, 100 mL oral dose of aluminum phosphate gel will reduce the gastrointestinal absorption of strontium-90 by 85%. Oral aluminum phosphate should be used if internal contamination with strontium-90 is expected [1,13,26-30].

Blocking Agents

Blocking agents block both the uptake and bioavailability of internal radionuclide contaminants. The most important blocking agent is potassium iodide, which is used for the treatment of internal contamination with iodine-125/131. Potassium iodide blocks the uptake of radioactive iodine by increasing the uptake of the nonradioactive
isotope. Because the thyroid gland is very sensitive to the effects of internal contamination with iodine-125/131, potassium iodine should be given as soon as possible after radioactive iodine exposure. It is recommended that patients take 300 mg of potassium iodide per day for 7 to 14 days following a potential iodine-125/131 exposure. Potassium iodide can also be taken prophylactically if there is sufficient warning of a potential iodine-125/131 exposure. The standard prophylactic regimen is a single 130 mg dose of potassium.

**Chelation Agents**

Chelation agents are the mainstay of treatment for internal radiation contamination. Chelation agents are substances that bind strongly with certain metals to form a stable, soluble complex that can be excreted by the kidneys. Diethylenetriaminepentaacetic acid (DTPA) is the most effective and commonly recommended chelation agent for the treatment of internal radiation contamination. DTPA complexes are very stable and water-soluble and are unlikely to release bound radionuclides before renal excretion. DTPA chelation therapy is especially effective for the treatment of internal radiation contamination with curium, americium, and plutonium. DTPA is administered as an intravenous solution of 1 g dissolved in 250 mL of saline or 5% glucose, infused over 1 hour per day for up to 5 days. The use of DTPA is contraindicated for the treatment of uranium-238/235 contamination because of an increased risk of renal damage. It is recommended that internal contamination with uranium-238/235 be treated with oral sodium bicarbonate, with the dose regulated to maintain an alkaline urine pH. Excretion of uranium-238/235 can be enhanced with the addition of a diuretic, such as furosemide [1,13].  

Dimercaprol is a chelation agent that is particularly useful for the treatment of internal contamination with polonium-210. Dimercaprol is a chelation agent for mercury poisoning. For polonium-210 contamination, 5 mg per kg of dimercaprol should be given initially, followed by 2.5 mg per kg two times daily for 10 days. Dimercaprol should be given by deep intramuscular injection only; it should not be given intravenously. Dimercaprol is very nephrotoxic and should always be used with caution. It is recommended that oral sodium bicarbonate be given to maintain an alkaline urine pH, which decreases the risk of nephrotoxicity by preventing the dissociation of the dimercaprol–polonium-210 complex in the urine. Serum creatinine and urine pH should be carefully monitored during treatment with dimercaprol [1,13,26-30].

**Need for Rapid Treatment**

To be most effective, treatment for internal contamination should begin
within hours after the radiation exposure. Early information on the history of a radiation exposure incident may or may not identify the major isotopes involved. Patients will likely present with no clinical symptoms other than conventional trauma. Therefore, critical decisions regarding the initial, empirical treatment of potential internal radiation contamination may have to be based on the historical information that is provided. It is imperative that physicians who could be involved in the management of radiation casualties be familiar with the agents used for the treatment of the most likely internal radiation contaminants. These agents are summarized in Table 129.3.

DECONTAMINATION

To prevent contamination of other patients and medical staff, radiation casualties must be decontaminated before admission into a hospital. However, life-saving emergency medical care should be performed as soon as possible and before decontamination takes place. Therefore, a special emergency treatment area, where potentially contaminated patients can be treated and stabilized, will have to be set up outside the hospital. Once a patient has been stabilized, decontamination can occur in another specially designated area that is also outside the hospital. It is recommended that the designated decontamination area be at least 50 yards downwind from the hospital or another treatment area.

All health care workers should protect themselves with scrubs, gowns, masks, double gloves, and shoe covers during the treatment and decontamination of radiation casualties. These measures provide sufficient protection from most radioactive isotopes that could be contaminating a patient. It is recommended that health care workers continue to observe these measures after decontamination of a radiation casualty because it is possible that the decontamination could be incomplete, and residual radioactive material could remain on or in the patient. It is best to assume that every patient near a radiation exposure event has been contaminated, even if no radiation is detected by a radiac meter. Such patients should be decontaminated as usual, and members of the decontamination team and medical treatment staff should wear protective clothing.

The decontamination process is quite simple. All of the patient’s clothing must be removed and discarded into a clearly labeled and secure container so that it does not further contaminate people and surroundings after removal. If the clothing needs to be cut off the patient, the scissors should be washed with soap and water between each cut to avoid spreading contamination on subsequent cuts. After all the clothing has been removed, the patient is thoroughly washed with soap and water. This simple soap-and-water process has been shown to be effective in removing more than 95% of external residual radioactive material from radiation-exposed patients [1,13,26-30].

Once a radiation-exposed patient has been stabilized and decontaminated, he or she should be admitted into the hospital or another treatment facility for definitive care. Again, it is best to assume that hospitalized radiation-exposed patients may still be contaminated, even after the decontamination process has been completed. It is recommended that all radiation casualties be admitted to specially designated areas of the hospital and that the staff of these areas should
wear appropriate protective clothing, as described earlier.

Patients exposed to potentially life-threatening doses of radiation will require critical care management during the manifest illness phase of an acute radiation subsyndrome. To reduce the potential for radioactive contamination, it is recommended that such patients be cared for in specially designated areas of intensive care units or in a designated hospital area that has been converted to an intensive care unit for the management of radiation casualties.

OVERVIEW

Ancient use of contaminated water, animal carcasses, and toxins used as tools against enemy forces date as early as prehistoric times and the first evidence of mass use was in 184 BCE when Hannibal ordered serpent-filled pots to be hurled onto enemy decks in the naval battle of Eurymedon. The pots shattered, and the ensuing chaos gave victory to the Carthaginians. During the French and Indian War in 1763, British Captain Ecuyer used “two Blankets and a Handkerchief from the Smallpox Hospital” intentionally as a biologic agent to weaken Native Americans supportive of the French, leading to outbreaks of smallpox
among tribes in the Ohio region [1]. German, Japanese, British, and American forces all evaluated the potential use of bioweapons during World War I. Bioterrorism remains an active concern today owing to discoveries of Al-Qaeda laboratories for biologic weapons in Iraq and sporadic criminal events such as the October 2001 anthrax attacks in the US mail, leading to 22 cases of anthrax and five deaths [2,3]. These attacks demonstrate the need for clinicians to be prepared to deal with bioterrorism attacks in their respective communities. Additionally, the concept of “biocrime” is important for clinicians to distinguish, where there is a malevolent motivation to use a biologic agent against an individual person [4].

The Center for Disease Control (CDC) categorizes potential bioterrorism agents based on their severity, availability, and potential for widespread harm in the event of release. The agents in each category are summarized in Table 130.1. Category A agents have the greatest potential for the production of mass casualties and a major adverse public health impact. Category B agents have some potential for large-scale dissemination and mass casualties, but would be expected to cause less illness and death than Category A agents. Category C agents are those that do not pose a high bioterrorism threat at the present time but could emerge as a future threat. This chapter focuses on Category A agents that have the greatest ability to cause mass casualties and significant loss of life. However, some Category B agents, such as ricin, are also discussed because of their potential to be used as clandestine agents of terrorism [5,6]. Table 130.2 provides the clinician some useful Emergency Response Phone Numbers in case there is suspicion of an incident.

SMALLPOX

The last case of endemic smallpox occurred in Somalia in 1977. In 1980, the World Health Organization (WHO) declared that the disease was eradicated. However, in recent years there has been renewed concern about the variola virus, the causative agent of smallpox, primarily owing to the potential of the variola virus to be used as a biologic weapon of mass destruction. As a result of this concern, the WHO has restricted the number of laboratories officially authorized to serve as repositories for the variola virus to two: the CDC in Atlanta, Georgia, and the Vektor Institute in Novosibirsk, Russia [7,8].

Although smallpox has been officially declared to be eradicated, there is a possibility for its reemergence. Live smallpox virus has been inadvertently stored in laboratories from past experiments, leading to the potential for accidental release [9]. There is historical evidence of smallpox virus survival in interred and exhumed individuals from the 18th century [10].

The US military began vaccination of deploying forces against smallpox on December 13, 2002 [11]. Much has been learned regarding the indications, contraindications, and efficacy of the vaccine since this mass immunization process began. Considerable thought has also been given to the dire consequences of a smallpox attack and the preparations necessary to manage a large-scale epidemic resulting from such an attack [12,13]. This section focuses on those aspects of smallpox infection that are most relevant to the critical care physician.

Virology

The causative agent of smallpox, the variola virus, is a member of the Poxviridae family, subfamily Chordopoxvirinae, and genus Orthopoxvirus. This genus also includes vaccinia (used in the smallpox vaccine), monkey pox virus, camel pox, and cowpox. The variola virus, like other members of the Poxviridae family, is a large, enveloped, deoxyribonucleic acid (DNA) virus. Poxviridae are the only viruses that can replicate in the cytoplasm of cells without involvement of the cell nucleus. The variola virus has a brick-shaped morphology, measures 260 by 150 nm, and has one of the largest viral genomes known. Its large genome makes it difficult to genetically engineer or synthesize the virus in the laboratory. Humans are the only known reservoir for the variola virus, although monkeys are susceptible to infection [14]. The variola virus is very stable and maintains infectivity for long periods of time outside the human host [15]. There are two strains of variola, variola
major and variola minor. Variola major is more virulent with a mortality rate between 20% and 50% in infected individuals. Variola minor causes a similar illness, but the mortality is less than 1% [16].

Transmission and Pathogenesis

Transmission of variola occurs from person to person by the dispersion of respiratory droplet nuclei. Transmission is enhanced by infected individuals who have a cough, however, detailed dispersal and pathogenic mechanisms are unclear owing to limited technologic tools available when smallpox was an endemic human disease [17]. Although infrequent, infection has also been known to occur following contact with infected clothing, bedding, or other contaminated fomites [18].

Following inhalation, the variola virus seeds the mucus membranes of the upper and lower respiratory tract and then migrates to regional lymph nodes, where viral replication occurs. Viral replication in regional lymph nodes leads to viremia, which results in systemic dissemination of the virus to other organs including the liver, spleen, skin, lung, brain, and bone marrow, where it continues to replicate. Clinical symptoms typically develop after an incubation period of 7 to 17 days. Following the initial infection period of 1 to 4 days in which viremia occurs, the clinical manifestations of smallpox appear in a series of distinct phases. These phases are uniquely characteristic of smallpox and are summarized in Table 130.3.

| TABLE 130.3 |
| Smallpox Disease | Smallpox Signs and Symptoms |
| Incubation period | Exposure to the virus is followed by an incubation period during which people do not have any symptoms and may feel fine. This incubation period averages about 12 to 14 d but can range from 7 to 17 d. During this time, people are not contagious. |
| (Duration: 7 to 17 d) Not contagious | |
| Initial symptoms (Prodrome) | The first symptoms of smallpox include fever, malaise, head and body aches, and sometimes vomiting. The fever is usually high, in the range of 101 to 104°F. At this time, people are usually too sick to carry on their normal activities. This is called the |
| (Duration: 2 to 4 d) Sometimes contagious | |
prodrome phase and may last for 2 to 4 d. A rash emerges first as small red spots on the
tongue and in the mouth. These spots develop into sores that break open and spread large amounts of the virus into the mouth and throat. At this time, the person becomes most contagious.

Early rash
(Duration: about 4 d)
Most contagious

Rash distribution:
View enlarged image.

Around the time the sores in the mouth break down, a rash appears on the skin, starting on the face and spreading to the arms and legs and then to the hands and feet. Usually the rash spreads to all parts of the body within 24 h. As the rash appears, the fever usually falls and the person may start to feel better.

By the third day of the rash, the rash becomes raised bumps.

By the fourth day, the bumps fill with a thick, opaque fluid and often have a depression in the center that looks like a bellybutton. (This is a major distinguishing characteristic of smallpox.)

Fever often will rise again at this time and remain high until scabs form over the bumps.

Pustular rash
(Duration: about 5 d)
Contagious

The bumps become pustules—sharply raised, usually round and firm to the touch as if there’s a small round object under the skin. People often say the bumps feel like BB pellets embedded in the skin.

The pustules begin to form a crust and then scab.

By the end of the second week after the rash appears, most of the sores have scabbed over.

Resolving scabs
(Duration: about 6 d)
Contagious

The scabs begin to fall off, leaving marks on the skin that eventually become pitted scars. Most scabs will have fallen off 3 wks after the rash appears.

The person is contagious to others until all of the scabs have fallen off.
Scabs resolved  
Not contagious

Scabs have fallen off. Person is no longer contagious.

Smallpox may be contagious during the prodrome phase, but is most infectious during the first 7 to 10 days following rash onset. From [https://www.cdc.gov/smallpox/symptoms/index.html](https://www.cdc.gov/smallpox/symptoms/index.html). Accessed September 17, 2016; [https://upload.wikimedia.org/wikipedia/commons/6/6a/Smallpox_%28variola_orthopox_virus_%29_Early_Rash_vs_chickenpox.gif](https://upload.wikimedia.org/wikipedia/commons/6/6a/Smallpox_%28variola_orthopox_virus_%29_Early_Rash_vs_chickenpox.gif).

Unlike varicella, the skin lesions of smallpox are mostly of the same type and same stage of development throughout each clinical phase (Figs. 130.1 and 130.2). In contrast, the skin lesions associated with varicella are greatest on the trunk, spare the hands and soles, and are at multiple stages at any given time, with papules, vesicles, and crusts all present simultaneously.

**FIGURE 130.1** Smallpox pustular phase
umbilicated lesions

The mortality rate from the usual variety of smallpox is 3% in vaccinated individuals and 30% in the unvaccinated. Death from smallpox is presumed to be secondary to overwhelming quantities of immune complexes and soluble variola antigen. This smallpox-associated systemic inflammatory response results in severe hypotension during the second week of illness. Respiratory complications, such as pneumonia, and secondary bacteremia are common. Severe intravascular volume and electrolyte imbalances may occur, along with associated acute kidney injury. Rare secondary manifestations include encephalitis, arthritis, and orchitis [16].

Two atypical manifestations of smallpox have very high mortality rates. Hemorrhagic smallpox occurs in less than 3% of infected individuals. The hemorrhagic form is characterized by a short incubation period and an erythematous skin eruption that later becomes petechial and hemorrhagic, similar to the lesions seen in meningococcemia. Most individuals with the hemorrhagic form of smallpox die in 5 to 6 days after onset of the rash. The malignant form, or “flat smallpox,” is characterized by a fine-grained, reddish, nonpustular, and confluent rash, occasionally with hemorrhage. The malignant form occurs in 2% to 5% of infected individuals. Affected patients have severe systemic illness and most die within several days. Pulmonary edema occurs frequently in both hemorrhagic and malignant smallpox, contributing to the high mortality rates [16,18].

The primary long-term sequela of smallpox is the “pockmarks” that affect the skin. These are pitted lesions that permanently scar the face.
owing to involvement of sebaceous glands. Panophthalmitis, viral keratitis, and corneal ulcers can cause permanent blindness in 1% of infected individuals. Infection with smallpox results in lifelong immunity [19].

**Diagnosis**

The differential diagnosis of papulovesicular lesions that can be confused with smallpox includes chickenpox (varicella), shingles (herpes zoster), disseminated herpes simplex, monkeypox, drug eruptions, generalized vaccinia, eczema vaccinatum, impetigo, bullous pemphigoid, erythema multiforme, molluscum contagiosum, and secondary syphilis. Severe varicella is the most common eruption that can be confused with smallpox. Table 130.4 delineates clinical features that can help to distinguish varicella from smallpox.

Confirmation of smallpox can be performed by the analysis of skin scrapings, vesicular fluid, or oropharyngeal swabs. Specimens should be collected using respiratory and contact isolation procedures, ideally by previously vaccinated personnel. Specimen collection techniques and guidelines are available from public health departments, the CDC, and the WHO [20]. https://www.cdc.gov/smallpox/lab-personnel/specimen-collection/specimen-collection-procedures.html.

The brick-shaped variola virus is distinguished from varicella-zoster by electron microscopy. However, polymerase chain reaction (PCR) assays are the mainstay of diagnosis at the present time. Serologic testing is not useful for differentiating the variola virus from other orthopoxviruses. Laboratory specimens should only be manipulated and processed at laboratories with Biosafety Level 4 facilities [12]. If smallpox is suspected, the local public health department must be notified immediately. Public health departments can provide valuable assistance in collecting specimens and getting them to an appropriate laboratory for analysis.

Infection Control

Although the primary transmission of smallpox is via respiratory droplet nuclei, infected clothing and bedding can also transmit disease [10]. Individuals with smallpox are most infectious within the first 7 to 10 days of the rash, but the disease is contagious until all crusted lesions have fallen off [16]. Secondary cases occur in family members or health care workers who are exposed to an infectious individual. It is estimated that the rate of transmission may be as high as six new cases for every infected person among unvaccinated contacts [21]. All individuals who have direct contact with the index case should be quarantined for 17 days in respiratory isolation. Home quarantine will be necessary during mass casualty situations. Health care workers caring for infected individuals should be vaccinated and use strict airborne and contact isolation procedures. Infected patients should be placed in respiratory and contact precautions and managed in a negative-pressure isolation room. Patients should remain under precautions until all crusted lesions have fallen off. Patients and exposed personnel should also be vaccinated if the disease is in the early stage. If performed early, vaccination may significantly decrease the severity of smallpox symptoms [19, 22].

Treatment

Cidofovir is an antiviral drug, currently approved in the US for use in cytomegalovirus retinitis. This agent has broad-spectrum in vitro activity against numerous DNA viruses, including orthopoxviruses in animal models. Cidofovir is a long-acting nucleotide analogue that must be administered intravenously and carries a high risk of nephrotoxicity,
requiring coadministration with oral probenecid to minimize this risk. Cidofovir given at the time of, or immediately following, exposure has the potential to prevent cowpox, vaccinia, and monkeypox. Aerosolized cidofovir has been shown to protect mice against intranasal challenge with the cowpox virus [23] and against rabbits undergoing rabbitpox challenge [24].

Other investigational agents with evidence of activity against variola include tecovirimat (ST-246), a novel inhibitor of orthopoxvirus egress from infected mammalian cells, and brincidofovir (CMX001), an oral lipid conjugate of cidofovir [25] (Table 130.5). Anti-vaccinia immune globulin decreases pulmonary viral loads and pneumonitis in animals with vaccinia or cowpox, but its benefit in smallpox is unproven [24,26–33].

**Immunization**

Smallpox vaccination is based on the principle of cross-immunity between variola and vaccinia, a derivative of the closely related cowpox...
virus (and the ultimate source of the word “vaccine”). Vaccination continues to be the mainstay of smallpox prevention. First-generation live virus vaccines (Dryvax, Aventis Pasteur Smallpox Vaccine [APSV], Lancy-Vaxina, and L-IVP) were effective, but at the cost of numerous side effects, reactions, and contraindications. Newer-generation vaccines include replication-competent vaccines such as ACAM2000 (Sanofi Pasteur) and the APSV (Aventis Pasteur), which are capable of replication in human cells, and Imvamune (Bavarian Nordic), a highly attenuated vaccinia strain which is incapable of replication in mammalian cells and is recommended for use in immunocompromised persons for whom ACAM2000 and APSV would be contraindicated. There has been considerable discussion regarding the efficacy of preexposure mass vaccination to protect the public against smallpox in the event of a bioterrorism attack. The CDC maintains three smallpox vaccines in the national stockpile: ACAM2000, Aventis Pasteur Smallpox Vaccine (APSV), and Imvamune [19]. Table 130.6 provides recommended usage.

The WHO and CDC instructions for the administration of smallpox vaccine are as follows:

**Site of vaccination:** Outer aspect of upper arm over the insertion of the deltoid muscle.

**Preparation of skin:** None, unless the site is obviously dirty. Use water to cleanse the site because the use of a disinfectant can kill the virus.

**Withdrawal of vaccine from the ampule:** A cool, sterile bifurcated needle is inserted into the reconstituted vaccine ampule. A droplet is sufficient for vaccination and is contained within the fork of the needle. Never dip the same needle back into the ampule to avoid contamination.

**Application:** The needle is held at 90 degrees perpendicular to the skin; the needle then touches the skin to release the droplet. For primary vaccination, three strokes are made in a 5-mm area. For revaccination, 15 up/down, perpendicular strokes of the needle are rapidly made in the area of 5 mm diameter (through the drop of vaccine deposited on the
Dressing: Although the WHO does not recommend a dressing, the CDC recommends a loose sterile gauze dressing covered by a semipermeable dressing to prevent transmission of the virus. Absorb the excess blood and vaccine with gauze, and dispose the gauze in a biohazard receptacle.

Unused vaccine: Unused vaccine is good for 90 days after reconstitution and should be refrigerated without any special light precautions.

The most common adverse reactions following smallpox vaccination are tenderness and erythema at the injection site and secondary bacterial infections [34]. Inadvertent autoinoculation of another body site, generalized vaccinia (vesicles or pustules appearing on normal skin distant from the vaccination site), eczema vaccinatum, vaccinia keratitis, encephalitis, and progressive vaccinia have been reported in primary vaccinations. A review of approximately 39,000 people vaccinated against smallpox (36% primary vaccinations and 64% revaccinations) reported the following adverse reactions: encephalitis in one individual, myopericarditis in 21 individuals, generalized vaccinia in two individuals, inadvertent inoculation in seven individuals, and ocular vaccinia in three individuals [35].

Myopericarditis was reported for 200 cases from a prior US military vaccination program, at a rate of 117 cases per million vaccines [11,36]. This postvaccination myopericarditis is likely to be immunologically mediated and not the result of direct viral infection of the myocardium. The reported rate of cardiac mortality is 1.1 deaths per million primary vaccines. Routine vaccination is not recommended for persons with known cardiac disease or three or more risk factors for coronary artery disease, but vaccination is recommended for persons following a known exposure or at high risk for exposure [19].

Contraindications to smallpox vaccination are infants less than 1 year of age; immune suppression; eczema; exfoliative skin conditions; pemphigus; cardiac disease as previously described; allergy to any component of the vaccine; and pregnant or breastfeeding women. Individuals who are taking high-dose corticosteroids should not be vaccinated within 1 month of completing corticosteroid therapy. Although testing for human immunodeficiency virus (HIV) is not mandatory prior to smallpox vaccination, HIV testing should be readily available to all
individuals considering smallpox vaccination [37,38]. Individuals with a contraindication to vaccination should avoid people who have been recently vaccinated, owing to possible transmission of vaccinia from viral shedding at the vaccination site. A small number of deaths (12/68) in the 1960s were attributed to unvaccinated persons exposed to recently vaccinated friends or family members [35].

Health care workers must be aware of the possibility for the nosocomial transmission of vaccinia during the hospitalization of a recently vaccinated patient. Nosocomial infection can result in mortality up to 11% [39,40]. Direct carriage of the virus on the hands, nasal mucosa, fomites, contaminated equipment, and laundry has been implicated in the transmission of vaccinia. Risk of the nosocomial transmission can be mitigated by several simple precautions. Semipermeable dressings should be applied to the site of a recent vaccination and changed frequently if there is evidence of the accumulation of purulent material. Gloves must be worn during dressing changes and meticulous handwashing with antimicrobial soap must be performed by all health care providers, both before and after contact with a recently vaccinated patient. Contaminated dressings should be disposed of in a biohazard container. Care should be taken to avoid contact of the vaccination site with material or equipment that could transmit the virus to other individuals. Clothing, towels, and other cloth materials that have contact with the site can be decontaminated by routine laundering with hot water. If at all possible, health care workers who are responsible for dressing changes should be vaccinated against smallpox, but nonvaccinated individuals are acceptable as long as appropriate precautions are observed [19,37].

Treatment of adverse effects following smallpox vaccination include supportive therapy, administration of vaccinia immune globulin, cidofovir, and an antiviral ophthalmic ointment, such as trifluridine or vidarabine, for eye involvement. Vaccinia immune globulin is available from the CDC, although the supply is limited. Cidofovir is available at no cost from the CDC under investigational use if a patient fails to respond to VIG, the patient is near death, or all inventories of VIG are depleted. The dose of cidofovir is 5 mg per kg, given intravenously, over 60 minutes as a single dose [41]. More recently, the oral prodrug of cidofovir, brincidofovir (CMX001), has been used in patients with disseminated vaccinia in combination with VIG and tecovirimat (ST-246) with reasonable outcomes [42]. Based on this limited human experience as well as animal data [26], it appears that combination therapy with VIG and either cidofovir or brincidofovir represents the best available therapy for disseminated vaccinia, and possibly for smallpox, at this time.

ACAM2000, a cell culture-derived smallpox vaccine that has demonstrated 94% efficacy in phase II clinical trials, was licensed by the
Federal Drug Administration (FDA) for administration to people at high risk of smallpox or other orthopoxvirus diseases in 2007. Over 200 million doses of the vaccine have been purchased by the US Strategic National Stockpile (covering approximately 62% of the population), but it is not available for commercial use. Clinical trials show similar efficacy and side effects profile to the older Dryvax vaccination, but ACAM200 cannot be diluted [43].

In the event of an intentional release of variola virus, the priority of vaccination (Table 130.6) is as follows [19]:

*Group 1*: Individuals directly exposed to the release.

*Group 2*: Individuals with face-to-face household contact with a directly exposed individual.

*Group 3*: Personnel directly involved in the evaluation, care, or transport of infected patients.

*Group 4*: Laboratory personnel responsible for handling and processing specimens, and others who may be exposed to infectious materials.
ANTHRAX

In the fall of 2001, 22 cases of anthrax with five deaths occurred in the USA as a result of anthrax spores in envelopes sent through the US mail. Early recognition and treatment of anthrax by astute clinicians was responsible for preventing additional deaths [2,3]. Identification of a single case should prompt notification of local, state, and national public health authorities. The CDC and US military have rapid response teams with specialized expertise, training, and equipment that can be deployed immediately to assist local authorities in the event of a bioterrorism attack [44]. Cases of endemic anthrax occur in developing countries worldwide, with sporadic cases occurring in industrialized countries owing to occupational exposure or illegal drug abuse.

Microbiology

*Bacillus anthracis* is a large, gram-positive, aerobic, spore-forming, nonmotile bacillus as shown in Figure 130.3. The endospore form of *B. anthracis* is found in the soil of many regions of the world. Its virulence is determined by two plasmids. One plasmid involves the synthesis of a poly-D-glutamic acid capsule that inhibits phagocytosis of vegetative bacilli and the other contains genes for the synthesis of exotoxins. The exotoxins are known as protective antigen, edema factor, and lethal factor. The protective antigen is a binding protein that is necessary for entry into the host cell and combines with both edema factor and lethal factor to produce “edema toxin” and “lethal toxin” [45]. Edema toxin converts adenosine triphosphate to cyclic adenosine monophosphate (cAMP), resulting in high intracellular cAMP levels that impair water homeostasis and thereby cause cellular edema. Lethal toxin stimulates the overproduction of cytokines, primarily tumor necrosis factor-α and interleukin-1-β that cause macrophage lysis. The sudden release of inflammatory mediators appears to be responsible for the marked clinical toxicity of the bacteremic form of anthrax [46].
Clinical Manifestations

There are three major forms of anthrax infection. The clinical characteristics of each form are determined by the route of entry of the anthrax spores. *Cutaneous anthrax* is the most common naturally occurring form, comprising approximately 95% of cases. Spores enter the body through breaks in the skin and germinate within days, resulting in soft tissue or mucosal edema and localized necrosis. Initially, a painless, pruritic papule appears as in Figure 130.4, followed by vesiculation, ulceration, and a black, “coal-like” painless eschar as shown in Figure 130.5, thereby demonstrating the origin or the name, anthrax (*anthrax* is the Greek term for coal). A surrounding rim of nonpitting edema may distinguish the eschar of anthrax from other diseases, such as typhus. The eschar sloughs within 2 to 3 weeks of onset [47]. Abscess formation occurs only with superinfection. Painful proximal lymphadenopathy and lymphangitis may accompany the primary lesion. Cutaneous anthrax may spread hematogenously with significant morbidity and death in a small number of individuals. Cutaneous anthrax has been reported to cause microangiopathic hemolytic anemia, renal dysfunction, and coagulopathy.
Gastrointestinal and oropharyngeal anthrax usually occur following the ingestion of contaminated meat. This is a rare manifestation of anthrax, with most cases occurring in Africa. Mucosal ulcers, edema, and regional lymphadenopathy are initial manifestations. In the oropharyngeal form, pseudomembranes are seen in the oropharynx and upper airway obstruction can develop. In the gastrointestinal form, a necrotizing infection progresses from the esophagus to the cecum. Fever, nausea, vomiting, abdominal pain, gastrointestinal bleeding, and bloody diarrhea are typical symptoms. Death results from intestinal perforation or sepsis.

**FIGURE 130.4** Cutaneous anthrax papule.

The third form of anthrax infection is *inhalational anthrax*. Anthrax spores are 1 to 1.5 μm in size and easily deposit in the alveoli following inhalation. There, the endospores are phagocytosed by the pulmonary macrophages and transported via lymphatics to the mediastinal lymph nodes, where they may remain dormant as “vegetative cells” for approximately 10 to 60 days or longer. Once germination in the lymph nodes is complete, bacterial replication occurs. The replicating bacteria release edema and lethal toxins that produce a hemorrhagic mediastinitis.

Inhalational anthrax may present as a biphasic illness, with the initial syndrome resembling an upper respiratory tract infection to include fever, chills, fatigue, nonproductive cough, nausea, dyspnea, chest pain, and myalgias (*Table 130.7*). These symptoms typically last for 2 to 3 days and then progress to a more severe, fulminant illness. Meningitis should be considered early in the evaluation, because its presence may warrant more aggressive therapy [44]. Almost 50% of patients with inhalational anthrax develop hemorrhagic meningitis as a result of the hematogenous...
spread of *B. anthracis*. Dyspnea and shock characterize the fulminant phase of inhalational anthrax, although the severity of presentation may vary based on inoculum size and underlying host factors [49]. Chest radiographs show mediastinal widening and pleural effusions that may be massive. *B. anthracis* bacilli, bacillary fragments, and anthrax antigens can be identified by immunohistochemistry testing of the pleural fluid [50]. Although parenchymal infiltrates are not prominent, a focal hemorrhagic necrotizing pneumonitis was noted in 11 of 42 autopsy patients from the accidental release of anthrax in Sverdlovsk, USSR, in 1979. Massive bacteremia causes overwhelming septic shock and death within hours after the onset of symptoms [51]. The lethal dose to kill 50% of persons exposed (LD$_{50}$) to weapons-grade anthrax is reported as 2,500 to 55,000 spores, but as few as one to three spores may be sufficient to cause infection and estimates vary [45,52].

### Diagnosis

A high index of suspicion is necessary to make the diagnosis of anthrax. Laboratory findings from the US outbreak in 2001 showed that patients had a mild neutrophil-predominant leukocytosis, in the range of 7,500 to

13,300 per μL. Peak white blood cell count during illness ranged from 11,900 to 49,600 per μL. Elevated transaminases, hyponatremia, and hypoxemia were also noted [53,54]. All of these patients had abnormal chest radiographs with mediastinal widening, pleural effusions, consolidation, and infiltrates predominating. When present, mediastinal widening should be considered diagnostic of anthrax until proven otherwise, although computed tomography may be necessary to confirm its presence [54,55]. Hemorrhagic necrotizing lymphadenitis and mediastinitis are pathognomonic of anthrax but are typically only noted on autopsy. *B. anthracis* is easily cultured from blood, cerebral spinal fluid, ascites, and vesicular fluid with standard microbiology techniques. The laboratory must be notified when the diagnosis of anthrax is being considered, because many hospital laboratories will not further characterize *Bacillus* species unless requested. Biosafety Level 2 conditions apply for workers handling specimens, because most clinical specimens have spores in the vegetative state that are not easily transmitted. The presence of large gram-positive rods in short chains that are positive on India ink staining is considered presumptive of *B. anthracis* until the results of cultures and other confirmatory tests are obtained. Confirmatory testing can be performed by the CDC Laboratory Response Network. Rapid detection tests based on immunohistochemistry and PCR techniques are available via the Laboratory Response Network [56]. Nasal swabs are only useful for determining exposure in large groups of exposed persons; they have no role in individual diagnosis. In June 2004, the FDA approved the Anthrax Quick ELISA test (Immunetics, Inc., Boston, MA) that detects antibodies to the protective antigen of *B. anthracis* exotoxin. The test can be completed in less than 1 hour and is available to hospital and commercial laboratories by the manufacturer [56].

**Treatment**

Owing to the fulminant course of systemic anthrax, prompt initiation of therapy is essential for survival. Meningitis is a common complication of systemic anthrax and must be either excluded by lumbar puncture or treated empirically [57].

Systemic anthrax should be divided into meningeal and nonmeningeal disease for purposes of initial therapy. Current guidelines for the management of anthrax recommend the combination of an intravenous fluoroquinolone (ciprofloxacin, levofloxacin, or moxifloxacin) with a carbapenem (meropenem or imipenem) and either a protein-synthesis inhibitor (clindamycin or linezolid) or rifampin (an RNA polymerase inhibitor with similar efficacy as the traditional protein-synthesis inhibitors). Once meningitis has been excluded, either a quinolone or a
carbapenem may be used; combination therapy is not necessary in that setting. Carbapenems may be replaced with intravenous penicillin G or ampicillin once penicillin susceptibility has been confirmed. Doxycycline may be used in lieu of clindamycin or linezolid in less-severe, nonmeningeal disease. Tables 130.8 and 130.9 provide dosage summaries.

| TABLE 130.8 Intravenous Treatment for Systemic Anthrax with Possible/Confirmed Meningitis |
|-----------------------------------------|--------------------------------------------------------------------------------------|
| Bactericidal agent (fluoroquinolone)    | Ciprofloxacin, 400 mg every 8 h                                                      |
|                                         | Or                                                                                    |
|                                         | Levofloxacin, 750 mg every 24 h                                                     |
|                                         | Or                                                                                    |
|                                         | Moxifloxacin, 400 mg every 24 h                                                     |
| Plus                                    | Bactericidal agent (β-lactam)                                                       |
|                                         | For all strains, regardless of penicillin susceptibility or if susceptibility is unknown |
|                                         | Meropenem, 2 g every 8 h                                                            |
|                                         | Or                                                                                    |
|                                         | Imipenem, 1 g every 6 hATES                                                         |
| Alternatives for penicillin-susceptible strains only | Penicillin G, 4 million units every 4 h                                               |
|                                         | Or                                                                                    |
|                                         | Ampicillin, 3 g every 6 h                                                            |
| Plus                                    | Protein synthesis inhibitor                                                          |
|                                         | Linezolid, 600 mg every 12 h                                                        |
|                                         | Or                                                                                    |
|                                         | Clindamycin, 900 mg every 8 h                                                       |
|                                         | Or                                                                                    |
|                                         | Rifampin, 600 mg every 12 h                                                         |
|                                         | Or                                                                                    |
|                                         | Chloramphenicol, 1 g every 6–8 h                                                     |

Duration of treatment: ≥2–3 wks until clinical criteria for stability are met (see text). Patients exposed to aerosolized spores will require prophylaxis to complete an antimicrobial drug course of 60 d from onset of illness. Systemic anthrax includes anthrax meningitis; inhalation, injection, and gastrointestinal anthrax; and cutaneous anthrax with systemic involvement, extensive edema, or lesions of the head or neck. Preferred drugs are indicated in boldface.
a Increased risk for seizures associated with imipenem/cilastatin treatment.

b Linezolid should be used with caution in patients with thrombocytopenia. Linezolid use for >14 d has additional hematopoietic toxicity.

c Rifampin is not a protein synthesis inhibitor. However, it may be used in combination with other antimicrobial drugs on the basis of its in vitro synergy.

d Should only be used if other options are not available because of toxicity concerns.

---

### TABLE 130.9 Intravenous Therapy for Systemic Anthrax When Meningitis Has Been Excluded

**Bactericidal drug**

For all strains, regardless of penicillin susceptibility or if susceptibility is unknown

- Ciprofloxacin, 400 mg every 8 h
- Or
- Levofloxacin, 750 mg every 24 h
- Or
- Moxifloxacin, 400 mg every 24 h
- Or
- Meropenem, 2 g every 8 h
- Or
- Imipenem, 1 g every 6 h†
  - Or
  - Vancomycin, 60 mg/kg/d intravenous divided every 8 h
    - (maintain serum trough concentrations of 15–20 μg/mL)

**Alternatives for penicillin-susceptible strains**

- Penicillin G, 4 million units every 4 h
  - Or
- Ampicillin, 3 g every 6 h
  - Plus
- Protein synthesis inhibitor
- Clindamycin, 900 mg every 8 h
Or
Linezolid, 600 mg every 12 h‡
Or
Doxycycline, 200 mg initially, then 100 mg every 12 h§
Or
Rifampin, 600 mg every 12h

Duration of treatment: for 2 wks until clinical criteria for stability are met. Patients exposed to aerosolized spores will require prophylaxis to complete an antimicrobial drug course of 60 d from onset of illness. Systemic anthrax includes anthrax meningitis; inhalation, injection, and gastrointestinal anthrax; and cutaneous anthrax with systemic involvement, extensive edema, or lesions of the head or neck. Preferred drugs are indicated in boldface.

a Increased risk for seizures associated with imipenem/cilastatin treatment.
b Linezolid should be used with caution in patients with thrombocytopenia because it might exacerbate it. Linezolid use for >14 d has additional hematopoietic toxicity.
c A single 10–14 d course of doxycycline is not routinely associated with tooth staining.
d Rifampin is not a protein synthesis inhibitor. However, it may be used in combination with other antimicrobials drugs on the basis of its in vitro synergy.

There are limited data regarding treatment of pregnant women for anthrax, but anthrax infection is associated with both maternal and fetal death. Patients who are pregnant, postpartum, or lactating should therefore receive the same treatment as nonpregnant adults with only a few exceptions. Fluoroquinolones (ciprofloxacin, levofloxacin, or moxifloxacin) should be given to pregnant women for both postexposure prophylaxis and treatment unless otherwise contraindicated. Doxycycline is relatively contraindicated in pregnancy and should only be considered if ciprofloxacin is unavailable or absolutely contraindicated. For systemic anthrax infection with possible or confirmed meningitis, a carbapenem (meropenem, imipenem, or doripenem) and protein synthesis inhibitor with good CNS penetration (linezolid, clindamycin, and rifampin) should be added to fluoroquinolone treatment. Therapy should continue for 60 days. Patients can be switched to oral therapy once stable. The use of systemic corticosteroids has been suggested for meningitis, severe edema, and airway compromise [58]. Cutaneous anthrax with systemic involvement; significant edema; and lesions of the head and neck should be treated similarly. Uncomplicated cutaneous anthrax can be treated
with oral ciprofloxacin or doxycycline for 7 to 10 days; however, owing to the possibility of concomitant inhalational exposure, a 60-day course is recommended [59,60].

A review of anthrax cases in adults from 1900 to 2004 noted that fulminant inhalational anthrax is often fatal despite advances in medical care. Early diagnosis, initiation of therapy and drainage of all effusions, improved survival and is pivotal for decreasing mortality in inhalational anthrax [54]. Similarly, a review of anthrax cases in children from 1900 to 2005 shows that early diagnosis and treatment of all forms of anthrax are critical for improved survival of children [61]. In the setting of a mass event, resources may become overwhelmed. In December 2015, the CDC Working Group for Anthrax Countermeasures proposed a “Clinical Framework and Medical Countermeasure Use During an Anthrax Mass-Casualty Incident” to be implemented only if triggered by local/state/federal authority [44]. Figure 130.6 shows the proposed triage algorithm (also see Chapter 127).
Crisis standards of care* framework for medical countermeasure prioritization among hospitalized persons with known or potential exposure to anthrax. The clinical algorithm addresses four decision points where resource limitations might impact clinical management during an anthrax mass-casualty incident. The first decision point involves diagnostic evaluation of anthrax meningitis, which is necessary to determine optimal antimicrobial therapy. The second decision point involves treatment regimens of combination intravenous antimicrobial therapy. The third decision point involves administration of antitoxins, as an adjunctive therapy. The fourth decision point involves the identification and drainage of fluid collections, which have been associated with a survival benefit. Local triage teams should be activated as outlined in the "IOM 2012 Crisis Standards of Care. Admission criteria for nonsystemically ill patients may depend on local and regional bed space. Clinicians may choose to administer a second oral antimicrobial for patients with nonspecific symptoms of anthrax who do not
meet criteria for hospitalization. Close follow-up is recommended. Patients with meningitis or in whom meningitis cannot be excluded should be treated aggressively and receive antitoxin even if an antitoxin shortage exists. Drainage of effusions improves survival. Clinicians experienced with management of effusions should assess for significant fluid collections and drain as possible under the current standard of care. Patients with meningitis or in whom meningitis cannot be excluded should receive a minimum of 14 days of IV antimicrobials before stepping down to single agent.

Prophylaxis

All patients exposed to anthrax should receive prophylaxis with oral ciprofloxacin (500 mg twice daily), levofloxacin (500 mg daily), or doxycycline (100 mg twice daily) for 60 days, regardless of laboratory test results. Nasal swabs can confirm exposure to anthrax, but cannot exclude it. High-dose penicillin or ampicillin may be an acceptable alternative for 60 days in patients who are allergic or intolerant to the recommended antibiotics [56]. More than 5,000 people received postexposure prophylaxis following the 2001 US outbreak, but only about half completed the 60-day course. The main reasons for discontinuing therapy were gastrointestinal or neurologic side effects (75%) or a low perceived risk (25%).

The anthrax vaccine (AVA-Biothrax) manufactured by BioPort Corporation in Lansing, Michigan, is the only licensed human anthrax vaccine in the USA. The vaccine consists of supernatant material from cultures of a toxigenic, nonencapsulated strain of B. anthracis. A six-dose series has been used by the US military. The anthrax vaccine is not available to the general public at the present time. Approximately 95% of vaccinated individuals seroconvert after the third dose of vaccine. There has been no conclusive evidence of lasting harm in over 1 million doses of anthrax vaccine given by the US military program, and the vaccine is generally considered to be safe by the FDA. A review by the US Army Medical Research Institute of Infectious Diseases reported a 1% (101/10,722) incidence of systemic symptoms, most commonly headache. Local or injection site reactions occurred in 3.6% [60]. A study comparing four subcutaneous injections of anthrax vaccine adsorbed (AVA) with three and four intramuscular injections of AVA showed similar immunoprotection at 7 months with fewer adverse effects at the injection site. Following an aerosolized B. anthracis attack, postexposure...
prophylactic vaccination and antibiotic therapy remain the most effective and least expensive strategies [56,62].

Adjunctive immunotherapy is available in the event of suspected or confirmed anthrax exposure. There are currently three products available, to be given in combination with antibacterial therapy: raxibacumab, a recombinant monoclonal antibody directed against the B. anthracis protective antigen (PA) [63,64]; obiltoxaximab, a humanized chimeric monoclonal antibody also directed against PA [65,66]; and Anthrax Immune Globulin Intravenous (AIGIV), which is a purified polyclonal preparation of anti-anthrax immunoglobulin derived from vaccinated human donors [67]. There are no head-to-head trials comparing these three products (and nor do any such trials appear likely), but all three have been recently approved by the FDA and are reasonable adjuncts to antimicrobial therapy and aggressive critical care in the treatment of anthrax.
TULAREMIA

Tularemia is a zoonosis caused by *Francisella tularensis*, an intracellular, nonspore-forming, aerobic gram-negative coccobacillus. Its primary reservoirs in nature are small mammals, such as rodents and rabbits. In the mid-20th century, both the USA and the former Soviet Union developed biologic weapons that could disperse *F. Tularensis* [68]. Although biologic weapons have now been banned, there remains concern that *F. tularensis* could be used as an agent of bioterrorism and has been speculated to have been used by Serbia against Kosovo in the 1990s [69,70]. In a 1970 report, the WHO estimated that 50 kg of aerosolized *F. tularensis* dispersed over a metropolitan area of 5 million people could cause 19,000 deaths and 250,000 incapacitating illnesses. The impact of such an attack would probably linger for several weeks to months because of disease relapses [71].

Microbiology

*F. tularensis* is a hardy organism that can survive in moist soil, water, and animal carcasses for many weeks. Chlorination of water prevents its spread through water contamination. *F. tularensis* can be aerosolized, and inhalation of aerosolized organisms poses a threat to those exposed. The most common isolate, and the most virulent form, is *F. tularensis* biovar *tularensis* (Group A). Inoculation or inhalation of as few as 10 organisms may cause clinical disease [70]. Transmission of *F. tularensis* to humans occurs predominantly through tick and flea bites, handling of infected animals, ingestion of contaminated food and water, and inhalation of the aerosolized organism. There is no human-to-human transmission. As a biologic weapon, the organism would most likely be dispersed as an aerosol, and cause mass casualties from an acute febrile illness that may progress to severe pneumonia [46,72].

Epidemiology

Tularemia occurs throughout the northern hemisphere, with highest incidence in Russia and Scandinavian countries. In the USA, tularemia cases are reported most often from the south-central and western states (Arkansas, Illinois, Missouri, Oklahoma, Tennessee, Texas, Utah, Virginia, and Wyoming). The predominant mode of transmission to humans in the USA is by tick bites, most often in spring and summer. Hunters and trappers exposed to animal reservoirs are at high risk for exposure [73]. In Europe and Japan, mosquito bites and the handling of
infected animals appear to cause the disease. A large outbreak of tularemia in 2003 along with small summer outbreaks between 1995 and 2005 in Sweden suggests environmental sources clustering around recreational areas [74]. An outbreak of tularemia on Martha’s Vineyard, Massachusetts, during the summer of 2000 was associated with lawn mowing and brush cutting [75]. A water-borne outbreak resulting in 21 cases of oropharyngeal and five cases of glandular tularemia was reported in the Republic of Georgia [76].

Pathogenesis

_F. tularensis_ enters the human host via the eye, respiratory tract, gastrointestinal tract, or a break in the skin. The virulence of the organism depends on its ability to replicate within the macrophage. On initial entry into the macrophage, _F. tularensis_ uses a bacterial acid phosphatase, AcpA, to inhibit the bactericidal respiratory burst response of the macrophage and continues to replicate in the host macrophage using IgIC, a 23-kDa protein that most likely affects Toll-like receptor-4 signal transduction in addition to other factors yet to be identified. Eventually, apoptosis of the macrophage occurs with the subsequent release of organisms resulting in secondary involvement of the local lymph nodes and bacteremia [70]. Once bacteremia develops, _F. tularensis_ infects the lungs, pleura, spleen, liver, and kidney. The host defense against _F. tularensis_ is T-cell independent in the first 3 days and T-cell dependent after 3 days of infection. On histopathology, granulomata with necrosis may be seen in infected organs. Following inhalational exposure, hemorrhagic airway inflammation may progress to pneumonia, pleuritis, and pleural effusion. The role of humoral immunity is uncertain.

Clinical Features

The clinical manifestations of tularemia depend on the site of entry, exposure dose, virulence of the strain, and host immune factors. Hematogenous spread may occur from any of the initial clinical presentations. Syndromes associated with tularemia are classified as primary pneumonic, typhoidal, ulceroglandular, oculoglandular, oropharyngeal, and septic. The _ulceroglandular form_ is the most common naturally occurring form of tularemia. After an incubation period of 3 to 6 days (range, 1 to 25 days) following a vector bite or animal contact, patients present with high fevers (85%), chills (52%), headache (45%), cough (38%), and myalgias (31%). They may also have malaise, chest pain, abdominal pain, nausea, vomiting, and diarrhea. A pulse-temperature dissociation (Faget’s sign) is often seen. At the site of inoculation, a tender papule develops that later becomes a pustule and
ulcerates as shown in Figure 130.7. Lymph nodes draining the inoculation site become enlarged and painful (85%). Infected lymph nodes may become suppurative, ulcerate, and remain enlarged for a long period of time. Exudative pharyngitis and tonsillitis may develop following ingestion of contaminated food or inhalation of the aerosolized organism. Pharyngeal ulceration and regional lymphadenopathy may be present. Systemic illness caused by *F. tularensis* without lymphadenopathy and presenting with fever, diarrhea, dehydration, hypotension, and meningismus is referred to as the *typhoidal form*.

The *pneumonic form* of tularemia may occur as a primary pleuropneumonia following the inhalation of aerosolized organisms. The pneumonic form may also occur as a result of hematogenous spread from other sites of infection or following oropharyngeal tularemia. After inhalational exposure, constitutional symptoms, such as fever and chills, typically precede the onset of respiratory symptoms. The respiratory symptoms include a dry or minimally productive cough, pleuritic chest pain, shortness of breath, and hemoptyhsis. Pleural effusions, either unilateral or bilateral, can occur. Pneumonic tularemia can rapidly progress to respiratory failure with acute respiratory distress syndrome,
multiorgan failure, disseminated intravascular coagulation, rhabdomyolysis, renal failure, and hepatitis [46,70]. Rarely, peritonitis, pericarditis, appendicitis, osteomyelitis, erythema nodosum, and meningitis have been reported to occur. Delays in diagnosis and failure to institute prompt aminoglycoside therapy result in higher morbidity and mortality. The mortality rate of untreated pneumonic tularemia is 60%, but with proper antibiotic therapy the mortality rate is significantly reduced to 1% to 2.5% [70,77].

Laboratory and Radiographic Findings

A high index of suspicion is needed in order to make an early diagnosis of tularemia. Lack of response to conventional treatment for skin ulcers or community-acquired pneumonia, along with a history of exposure to animals, may serve as diagnostic clues. Routine laboratory tests, such as a complete blood count and serum chemistry panels, are generally nondiagnostic. A complete blood count may show a leukocytosis with a normal differential or mild lymphocytosis. Mild elevations of lactic dehydrogenase, transaminases, and alkaline phosphatase may be seen on a serum chemistry panel. If rhabdomyolysis is present, an elevated serum creatine kinase concentration and urine myoglobin may be seen. Sterile pyuria has been reported. Mild abnormalities in cerebrospinal fluid cell counts, protein, and glucose have also been reported [70,77].

Tularemia can present with multiple abnormalities on a chest radiograph (Fig. 130.8). A report of the chest radiographic findings in 50 patients who had a confirmed diagnosis of tularemia showed the following abnormalities: patchy airspace opacities (74%, unilateral in 54%); hilar adenopathy (32%, unilateral in 22%); pleural effusion (30%, unilateral in 20%); unilateral lobar or segmental opacities (18%); cavitation (16%); oval opacities (8%); and cardiomegaly with a pulmonary edema pattern (6%). Rare findings such as apical infiltrates, empyema with bronchopleural fistula, miliary pattern, residual cyst, and residual calcification have been reported in less than 5% of patients [78].
Diagnosis

It is possible to isolate *F. tularensis* from sputum, blood, and other body fluids, but the organism can be difficult to culture on conventional media; cysteine or sulphydryl compounds are required for *F. tularensis* to grow. Notification of laboratory personnel that tularemia is suspected is mandatory, both to enhance the yield of culture and to ensure that appropriate biosafety procedures are observed. Routine diagnostic procedures can be performed in Biosafety Level 2 conditions. Examination of cultures in which *F. tularensis* is suspected may be done in a biologic safety cabinet, but procedures that might produce aerosols or droplets must be conducted under Biosafety Level 3 conditions [77].

Owing to the high infectivity and difficulty with cultures, serologic evaluation is often employed. Examination of secretions and biopsy specimens with direct fluorescent antibody or immunochemical stains may help to identify the organism. The diagnosis is often made through serologic testing using enzyme-linked immunosorbent assay (ELISA). Serologic titers may not be elevated early in the course of disease. A fourfold rise is typically seen during the course of illness. A single tularemia antibody titer of 1:160 or greater is supportive of the diagnosis [70,79]. Antibodies to *F. tularensis* may cross-react with other bacteria, such as *Brucella, Proteus*, and *Yersinia* species because of their particular
variant of endotoxin (a lipooligosaccharide), which decreases the specificity of serology-based assays. Antibiotic therapy can blunt the serologic response, which could mask the convalescent rise in titer needed to confirm the diagnosis. Antibody levels against *F. tularensis* can persist for years, so distinguishing between acute and remote infection also may be difficult.

The combined use of ELISA and confirmatory Western blot analysis was found to be the most suitable approach to the serologic diagnosis of tularemia [80,81]. Other diagnostic methods include antigen detection assays and PCR. A multitarget real-time TaqMan PCR assay (Applied Biosystems, Foster City, CA) has been reported to have high sensitivity and specificity for the diagnosis of tularemia and may be a valuable tool for the analysis of clinical specimens and field samples following a bioterrorism attack [82,83].

**Treatment**

The traditional treatment of choice for tularemia in adults is streptomycin, 10 to 15 mg per kg, given intramuscularly (IM) or intravenously (IV) twice daily. Gentamicin, 5 mg per kg, given IM or intravenously (IV) once daily, is an acceptable alternative. For children, the preferred antibiotics are streptomycin, 15 mg per kg, given IM twice daily (not to exceed 2 g per day) or gentamicin, 2.5 mg per kg, given IM or IV thrice daily. Alternate choices for adults with milder disease are doxycycline, 100 mg IV twice daily; chloramphenicol, 15 mg per kg, given IV four times daily; or ciprofloxacin, 400 mg, given IV or PO twice daily.

For children, alternate choices are doxycycline, 100 mg, given IV twice daily if the child weighs 45 kg or more, and doxycycline, 2.2 mg per kg, given IV twice daily for children weighing less than 45 kg. Chloramphenicol and ciprofloxacin can also be used as alternate antibiotics for children. The ciprofloxacin dose for children should not exceed 1 g per day. Gentamicin is preferred over streptomycin for treatment during pregnancy and chloramphenicol should not be given to pregnant patients. Treatment with streptomycin, gentamicin, or ciprofloxacin should be continued for 10 days. Treatment with doxycycline or chloramphenicol should be continued for 14 to 21 days.

Patients beginning treatment with doxycycline, chloramphenicol, or ciprofloxacin can be switched to oral antibiotics when clinically appropriate. β-Lactams and macrolides are not recommended for treatment of tularemia, but there has been two isolated case reports of glandular/abscess forms treated with a 6 week courses of cefuroxime or amoxicillin/clavulanic acid in pregnant women who refused first-line treatments [84].

In a mass casualty setting caused by tularemia, the preferred antibiotic
for adults and pregnant women is doxycycline, 100 mg, taken orally twice daily, or ciprofloxacin 500 mg, taken orally twice daily. For children, the preferred choices are doxycycline, 100 mg, taken orally twice daily if the child weighs 45 kg or more; doxycycline, 2.2 mg per kg, taken orally twice daily if the child weighs less than 45 kg; or ciprofloxacin, 15 mg per kg, taken orally twice daily and not to exceed 1 g per day. Treatment with ciprofloxacin should be continued for 10 days; treatment with doxycycline should be continued for 14 to 21 days. For immunosuppressed patients, either streptomycin or gentamicin is the preferred antibiotic in mass casualty situations [70].

Prophylaxis

Individuals exposed to F. tularensis may be protected against systemic infection if they receive prophylactic antibiotics during the incubation period. For postexposure prophylaxis, either doxycycline 100 mg, taken orally twice daily, or ciprofloxacin 500 mg, taken orally twice daily for 14 days, is recommended. Both doxycycline and ciprofloxacin can be taken by pregnant women for postexposure prophylaxis, but ciprofloxacin is preferred. Postexposure prophylaxis for children is the same as treatment during mass casualty situations [77].

Immunization

In Russia, a live attenuated vaccine has been used to offer protection to those living in tularemia-endemic areas and transferred to the USA in 1956. It is currently the only vaccine available under FDA Investigational New Drug Status and has been administered to hundreds since the 1950s by the US Army Medical Research Institute of Infectious Diseases (USAMRIID). Very few side effects from the scarification (similar to smallpox vaccine) occur and partial high-dose respiratory protection against the Type A strain has been shown. Novel investigational vaccines remain under development but are not yet available for clinical use owing to the difficulty of targeting a T-cell epitope against the intracellular F. tularensis pathogen [71,85].
PLAGUE

Few infectious diseases have had the same impact on human history and human biology as the plague. Similar to tularemia, plague is a zoonosis with a natural reservoir in rodents for which humans are incidental hosts. Multiple pandemics of plague are believed to have occurred since the 6th century CE, with the “Black Death” of the 14th century taking the lives of over 40 million people while leaving deep impressions in European and Asian culture, religion, and art [86]. The causative organism, *Yersinia pestis*, was identified by and ultimately named for French physician Alexandre Yersin during the 1894 plague epidemic in Hong Kong [87]. In recent years, the highly contagious nature of plague has raised concerns about its possible use as an agent of bioterrorism.

Microbiology

Plague is caused by *Yersinia pestis*, a gram-negative, nonmotile coccobacillus of the family Enterobacteriaceae, closely related to *Escherichia*, *Klebsiella*, and other enteric gram-negative organisms and sharing their typical bipolar “safety pin” staining appearance under Wright–Giemsa stains (Fig. 130.9). In common with other gram-negative bacilli, *Y. pestis* has a lipopolysaccharide endotoxin that mediates much of the exuberant host inflammatory response, with resulting sepsis, acute respiratory distress syndrome, and multiorgan failure [86,88]. In addition, *Y. pestis* carries three distinct plasmids responsible for much of its virulence: pYV/pCD1, which encodes for a secretion apparatus that permits the delivery of cytotoxins into mammalian host cells; pFra/pMT1, which encodes for the anti-phagocytic fimbrial antigen F1; and pPst/pPCP/pPla, which encodes for a plasminogen activator and other exotoxins permitting invasion of host tissues [89–91].
Y. pestis is naturally transmitted by the bite of a plague-infected flea, most commonly Xenopsylla cheopis, although the human body louse may play a role in human-to-human transmission in epidemics [92]. After ingestion of blood from an infected animal, bacteria multiply in the digestive tract of the flea and are then regurgitated into the next mammalian victim following a bite. Major reservoirs of plague in North America include the deer mouse, prairie dog and ground squirrel, but infections of domestic cats and dogs with secondary human cases have been reported in the past two decades [93–96]. Transmission to humans also occurs by direct contact with infected live or dead animals, inhalation of respiratory droplets from patients with pneumonic plague, or from direct contact with infected body fluids or tissue [86,89,97,98].

Plague as a Bioweapon

The history of biowarfare begins with the plague. In 1346, Mongol forces of the Golden Horde besieged the Genoese enclave of Kaffa on the Crimean peninsula. During the siege, the Golden Horde reportedly catapulted the corpses of plague victims into the city, an event which may have led to the introduction of plague to Western Europe and ultimately to the Black Death [99]. In more recent years, plague was developed as a bioweapon by the former Soviet Union, Imperial Japan, and the USA before the destruction of the US biologic weapon stockpile in the early
When used as a bioweapon, *Y. pestis* may produce differing syndromes depending on the mode of dispersal. Aerosol spread would be expected to produce pneumonic plague, whereas the release of infected fleas should lead to bubonic or septicemic plague [5,97,100]. Due the highly contagious nature of pneumonic plague, the WHO estimates that 50 kg of *Yersinia pestis* aerosolized over a population of 5 million people could result in 150,000 infections and 36,000 deaths from primary infections and secondary transmission [101]. The CDC currently classifies plague as a tier 1 threat agent, indicating a pathogen or toxin with maximum potential risk to public health in the event of release.

**Epidemiology**

Plague exists worldwide, with most of the 3,248 human cases reported to the WHO between 2010 and 2015 occurring in developing countries of Africa and Asia [102]. Since 2001, there have been a median of three human plague cases per year in the USA, with a mortality rate of 16% with appropriate antimicrobial and supportive treatments [103,104]. The majority of plague cases in the USA come from the states of Arizona, New Mexico, California, and Colorado, with rare cases from Texas and Oregon as shown in Figure 130.10. In the pre-antibiotic era, the plague mortality rate for the USA was approximately 66%, with increased mortality seen among ethnic minorities (91%) compared with non-Latino whites (53%). Since the advent of effective antibiotic therapy, no gender- or racial-associated differences in US plague mortality have been noted, however [104].
Pathogenesis

Human plague occurs in *bubonic, septicemic*, and *primary pneumonic* forms. After entering the body through a flea bite, bacteria migrate via cutaneous lymphatics to the regional lymph nodes and are subjected to phagocytosis. *Y. pestis* is taken up by host neutrophils and macrophages but evades destruction by phagocytosis through plasmid-encoded proteins such as Yops and F1 fimbrial antigen \([105,106]\). Surviving bacteria then proliferate intracellularly, with secondary spread through host lymphatics and ultimately progress to bacteremia and sepsis. Host tissue invasion is enhanced by the production of procoagulant and anticoagulant enzymes by the bacterium, including plasminogen activators \([91,107]\). The initial infection causes lymphadenitis and local swelling that is referred to as the “bubo” (hence, the name “bubonic plague”) (Fig. 130.11). These buboes contain dense concentrates of *Yersinia* bacilli along with necrosis. Bacterial modification of lipopolysaccharide helps evade host innate immunity by blunting the sensitivity of Toll-like receptor 4 to endotoxin, further facilitating bacterial proliferation and spread \([108]\). In the absence of therapy, bacteremia, sepsis, and death usually follow \([86,90,97]\).
In a minority of cases, primary **pneumonic plague** results from the inhalation of infected droplets, either from another infected host or from the aerosolization of a draining bubo. Human pneumonic plague resulting from transmission from infected animals has been reported [93,109]. Following inhalation, *Y. pestis* bacilli are engulfed preferentially by pulmonary macrophages before neutrophil recruitment takes place [110]. They are then transported to the lymphatic system and regional lymph nodes, with secondary bacteremia and seeding of the spleen, liver, skin, mucous membranes, and other organs [93,97,110]. **Primary septicemic plague** results from the direct inoculation of *Y. pestis* bacilli into the bloodstream, which presents with nonspecific signs similar to other acute febrile illnesses with sepsis. It is important to note that these entities may overlap; pneumonic and bubonic plague can and often do progress to septicemia. Rare forms of plague are **plague meningitis** and **plague pharyngitis**. Plague meningitis occurs following the hematogenous spread of *Y. pestis* bacilli to the meninges. Plague pharyngitis may occur following the ingestion or inhalation of *Y. pestis* bacilli [5].

**Clinical Presentation**
The incubation period and clinical manifestations of plague vary according to mode of transmission. 80% to 85% of plague cases diagnosed in the USA are bubonic, 10% to 12% are primary septicemic, and roughly 3% are primary pneumonic plague [103]. Bubonic plague may progress to septicemic or pneumonic plague in 23% and 9% of cases, respectively. The clinical presentation of plague of children is similar to that of adults, although secondary progression to plague meningitis appears to be more common in children [86,92,103]. There is little data regarding unique manifestations of plague in pregnant women [111].

**Septicemic Plague**

A minority of patients exposed to *Y. pestis* develop septicemic plague, either as a primary form (without buboes) or secondary to the hematogenous spread of bubonic or primary pneumonic plague. Presenting features of septicemic plague are nonspecific and difficult to distinguish from other undifferentiated febrile syndromes, with fever, delirium, nausea, and hypotension being typical. Abdominal pain, hepatosplenomegaly, disseminated intravascular coagulation, and purpura fulminans have been reported, along with distal gangrene of the nose and digits, similar in appearance to meningococcemia. Without rapid treatment, the disease progresses to septic shock, anuria, and the acute respiratory distress syndrome. The untreated mortality rate of septicemic plague has been reported as high as 93% to 100% [86,104].

**Pneumonic Plague**

Plague is highly contagious by the airborne route, and droplet precautions are mandatory for any patient suspected of having plague. Primary pneumonic plague occurs by inhaling infected droplets, which may result from respiratory transmission from another patient with pneumonic plague as well as from a draining bubo, and is characterized by a severe, rapidly progressive pneumonia and sepsis that is rapidly fatal if not treated promptly [97]. Buboes may develop in the cervical area. Acute respiratory failure requiring mechanical ventilation is common. Strict droplet isolation is mandatory. Chest radiographs most often show bilateral alveolar airspace opacities, although effusions and cavitation may occur [92,97,112]. Alveolar opacities in secondary pneumonic plague may have a nodular appearance consistent with hematogenous spread. Anterior mediastinal adenopathy is very rare in primary pneumonic plague, but hilar node enlargement is often present, a feature which may distinguish pneumonic plague from inhalational anthrax [5]. Similar to septicemic plague, the untreated mortality rate of primary pneumonic plague is 100% [97,104].
Secondary pneumonic plague occurs among approximately 12% of individuals with bubonic plague or primary septicemic plague following the hematogenous spread of *Y. pestis* bacilli to the lungs. It typically presents as a severe bronchopneumonia with cough, dyspnea, chest pain, and hemoptyisis. Chest radiographs show bilateral, patchy alveolar infiltrates that may progress to consolidation. In contrast to primary pneumonic plague, mediastinal, cervical, and hilar adenopathy may occur (Fig. 130.12) [86,97,112].

**FIGURE 130.12** A 38-year-old man from Himachal Pradesh was admitted with complaints of fever, cough, hemoptyisis, and dyspnea. There is endemic pneumonic plague owing to the prevalent custom of hunting wild rats and rodents. Sputum examination was positive for *Yersinia pestis*. The patient was successfully treated with antibiotics (Chest radiograph courtesy of Sanjay Jain, MD, Department of Internal Medicine, and Surinder K. Jindal, MD, Professor of Medicine, Postgraduate Institute of Medical Education and Research, Chandigarh, India.).
Diagnosis

The presence of a bubo in an ill patient should serve as an adequate clue for the majority of clinicians to the possibility of plague. Similar lesions and clinical syndromes may be seen with ulceroglandular tularemia (which raises similar concerns in regards to bioterrorism and is managed with comparable antimicrobial agents), epidemic typhus, suppurative infections (e.g., *Staphylococcus aureus*), and bartonellosis. The lesions of chancroid, lymphogranuloma venereum, syphilitic lymphadenitis, and mycobacterial disease may be grossly similar but present in a more subacute manner and generally without the severe illness and prostration seen with plague.

Conversely, the diagnosis of pneumonic and septicemic plague can be markedly more difficult given the absence of distinctive clinical findings. The radiographic findings of pneumonic plague are nonspecific, although the absence of mediastinal widening may help distinguish it from inhalational anthrax. The presence of the characteristic gram-negative rods in the sputum of an immunocompetent patient, particularly with a suitable exposure history, must raise the concern for plague. Primary septicemic plague’s high mortality is related in part to delays of diagnosis. Exposure history, purpura fulminans, septic shock, and acral gangrene are all consistent but strongly resemble the syndromes seen with meningococcemia; rickettsioses; and pneumococcal and pseudomonal sepsis [5,86,89,97,104,112].

Laboratory Diagnosis

A mild-to-moderate leukocytosis with neutrophil predominance and toxic granulations are seen in all forms of plague. In severe cases, elevated transaminases, azotemia, and coagulopathy with disseminated intravascular coagulation are seen. Gram stains of sputum; blood; or lymph node aspirates may show typical enteric gram-negative bacilli with bipolar staining, similar to *Escherichia coli*, *Klebsiella*, and other *Enterobacteriaceae*. Microscopic examination of a sputum specimen prepared with Wright–Giemsa stain will show the characteristic bipolar staining pattern more clearly (Fig. 130.10) [93].

*Y. pestis* will grow rapidly on conventional bacteriologic media. However, misidentification of *Y. pestis* has been described with automated bacterial identification devices [113]. With the increasing availability of mass spectrometry (matrix-assisted laser desorption/ionization time-of-flight, or MALDI-TOF) in clinical laboratories, these errors should be less frequent [114]. Rapid diagnostic tests such as immunoglobulin-M immunoassay, direct fluorescent antibody testing, and PCR are available through the CDC, Department of
Defense laboratories (including the US Army Research Institute for Infectious Diseases), and state public health laboratories. Rapid plague detection through the use of multiplex PCR panels (which also often include primers for multiple potential bioterror agents) are available and are highly sensitive [115]. Direct fluorescent antibody staining for Yersinia pestis (Fig. 130.13) and dipstick antigen detection tests are highly specific and are available at some centers. Rapid diagnostic assays using monoclonal antibodies to the F1 capsular antigen show promise for the early on-site diagnosis of plague [116,117], as do monoclonal antibodies directed at detection of Y. pestis lipopolysaccharide [118]. Additional tests for detection and confirmation that are available through the Laboratory Response Network include PCR assays; molecular-based subtyping; and immunohistochemistry on formalin-fixed tissues.

![Fluorescence antibody positivity for Yersinia pestis is seen as bright, intense green staining around the bacterial cell](http://www.cdc.gov/ncidod/dvbid/plague/bacterium.htm).

**FIGURE 130.13** Fluorescence antibody positivity for Yersinia pestis is seen as bright, intense green staining around the bacterial cell

(From CDC Web site: http://www.cdc.gov/ncidod/dvbid/plague/bacterium.htm.).

Plague should be suspected among persons with symptoms of fever and lymphadenopathy if they reside in, or have recently travelled to, a plague-endemic area and if gram-negative and/or bipolar-staining coccobacilli are seen on a smear taken from affected tissues. The diagnosis of plague should be presumed if immunofluorescence staining of smear or material is positive for the presence of Y. pestis F1 antigen and/or a single serum specimen shows the anti-F1 antigen in a titer of greater than 1:10 by agglutination. A diagnosis of plague is confirmed if one or more of the following criteria are met: isolation of Y. pestis from a clinical specimen, a
single *Y. pestis* antibody titer of more than 1:128 dilution, a fourfold rise in paired sera antibody titer to *Yersinia pestis* F1 antigen (with the second assay obtained 6 to 8 weeks after convalescence), or if PCR-based testing of body fluids or tissues is positive for *Y. pestis*. Antibody susceptibility testing should be performed at a reference laboratory.

Plague as a bioterrorism agent should be suspected when multiple cases of severe and rapidly progressive pneumonic plague cases are seen with fulminant systemic symptoms and hemoptysis. Although pretreatment specimens should be obtained when possible, treatment of suspected plague should not be delayed while awaiting confirmatory results.

**Treatment**

Traditionally, streptomycin or gentamicin has been the mainstays of therapy for *Yersinia pestis*. Other acceptable antibiotics are ciprofloxacin, tetracycline, doxycycline, and chloramphenicol [5,86]. Methylprednisolone and imipenem have shown evidence of efficacy in murine models of plague but lack supporting human data at this time [119,120]. Antimicrobial resistance among *Y. pestis* has been reported but appears to be rare, with the great majority of clinical isolates maintaining susceptibility to the recommended agents [121–124]. The recommendations of the Working Group on Civilian Biodefense from the year 2000 remain the basis of current CDC guidance (Tables 130.10 and Click here to enter text. 130.11). For adult patients with plague in a small, contained casualty setting, recommended regimens include streptomycin 1 g IM, given twice daily; gentamicin, 5 mg per kg IM or IV, once daily; or a 2 mg per kg loading dose of gentamicin followed by 1.7 mg per kg IM or IV every 8 hours. The dosing of aminoglycosides must include adjustment for renal function. The duration of treatment is 10 to 14 days. Oral therapy may be initiated once a patient demonstrates clinical stabilization and improvement. Alternate therapy with fluoroquinolones can be used in either setting, although initial therapy should be intravenous. For breastfeeding mothers and infants, treatment with gentamicin is recommended, but tetracyclines and fluoroquinolones may be used if gentamicin is unavailable or otherwise inappropriate [125].

*All recommended antibiotics for plague have relative contraindications for use in children and pregnant women; however, use is justified in life-threatening situations.*

Mass Casualty Treatment and Prophylaxis

In a mass casualty situation from the intentional release of plague, the urgency to initiate prompt treatment of infected individuals, as well as prophylaxis for those exposed but uninfected, may cause a significant stress on health care capabilities. The ability to administer prompt parenteral streptomycin or gentamicin for symptomatic individuals is ideal, but may be limited. The Working Group on Civilian Biodefense recommends the use of ciprofloxacin 500 mg, taken orally twice daily or doxycycline 100 mg, taken orally twice daily for adults and pregnant women, both for treatment and postexposure prophylaxis. All individuals who come within 2 meters of a patient with pneumonic plague should receive postexposure prophylaxis. The recommendations of Table 130.12 are consensus-based for treating plague following an intentional release or bioterrorism attack and may not reflect FDA-approved use or indications [126].

### Immunization

There is no approved vaccine available in the USA at present. A killed, whole-cell vaccine against plague was available until 1999 for those at high risk for exposure, but this vaccine was not effective against pneumonic plague and was unlikely to provide adequate protection in a biowarfare setting. Current vaccines in development include adenovirus and *Salmonella* vectors encoding for *Yersinia* epitopes [126,127], oral subunit vaccines comprising F1 and rV antigens [128,129], and attenuated strains of the closely related but less virulent *Yersinia pseudotuberculosis* [130,131].

### Infection Control

Patients suspected of plague should be placed immediately into respiratory droplet precaution isolation, with access to the patient room restricted to essential staff. Gowns, gloves, surgical masks, and eye protection should be worn by all staff. Aerosolizing procedures should be kept to an absolute minimum and avoided if possible. Negative pressure isolation or N95 masks are not necessary for plague, although infections that may present similarly to pneumonic plague (e.g., SARS-associated coronvairus) may require negative pressure rooms or PAPRs, thus requiring a higher level of protection while diagnostic testing is underway. Following 48 hours of therapy with appropriate antibiotics and with clear clinical improvement, patients with both nonpneumonic plague and pneumonic plague may be removed from isolation [132]. Laboratory workers must be warned of potential plague infection owing to the risk of laboratory-acquired plague [98].
Botulinum is an extremely potent neurotoxin that inhibits acetylcholine release and is produced by *Clostridium botulinum*, an anaerobic, spore-forming gram-positive bacterium present in the soil. Botulinum toxin can be inactivated by temperatures above 85°C for 5 minutes, but *Clostridium* spores can survive temperatures of 105°C for up to 4 hours, although they are readily destroyed by chlorine. Spores may remain viable for over 30 years in a dry state and are resistant to ultraviolet light exposure [133]. The botulinum toxin is among the most poisonous substances known. It can cause a serious, life-threatening paralytic illness among exposed individuals, is easily produced in a laboratory, and can be easily transported. In view of these properties, botulinum toxin has been designated as a Category A bioterrorism threat by the CDC [5, 8]. There are reports that several countries may have stockpiled or are developing botulinum toxin for use as a bioweapon [133]. The general features and management of botulism are presented in Chapter 86 (ref 8th ed. Rippe), but the implications of botulism as a bioterrorist weapon are discussed here.

**Botulinum Toxin as an Agent of Bioterrorism**

There are three forms of naturally occurring botulism: *foodborne botulism*, *wound botulism*, and *intestinal (infant and adult) botulism*. All forms of botulism can produce a serious paralytic illness that can lead to respiratory failure and death.

Botulinum toxin solution is a colorless, odorless, tasteless liquid that is easily inactivated by heating at a temperature greater than 85°C for 5 minutes. There are seven different antigenic types: botulinum A, B, C, D, E, F, and G. Given its extreme potency, botulinum toxin could produce devastating effects and mass casualties, if intentionally dispersed by aerosol or used to contaminate the water supply [5, 133]. Botulinum toxin types A, B, E, and F have been associated with naturally occurring foodborne botulism. Types C and D botulinum toxin cause natural disease in birds and cattle. Type G botulinum toxin is found in South America, but it has not been associated with foodborne botulism. Inhalational challenge studies with aerosolized botulinum toxin of primates have demonstrated the development of illness following exposure to all seven toxins. Researchers suspect that humans are also susceptible to these types [134].

The intentional use of botulinum toxin can be either inhalational or foodborne. In the 1930s, the Japanese reportedly executed a number of
Manchurian prisoners by feeding them cultures of *Clostridium botulinum*. Botulinum toxin was produced by the USA for use as a bioweapon from World War II to the early 1970s when the bioweapon program was terminated. Following the 1972 Convention on the Prohibition of the Development and Stockpiling of Biological and Toxin Weapons, both the former Soviet Union and Iraq continued to develop botulinum toxin as a biowarfare agent. After the 1991 Persian Gulf War, Iraq admitted to UN weapons inspectors that it had produced and stockpiled biologic weapons containing botulinum toxin [134].

There remains considerable concern about the potential use of botulinum toxin as bioweapon. Contamination of either a food or a beverage source with botulinum toxin could result in mass casualties, overwhelming hospitals and intensive care units, and creating significant anxiety among the general population [134]. It has been estimated that 1 g of botulinum toxin added to milk that is commercially distributed and consumed by 568,000 individuals can result in 100,000 cases of botulism [135]. It has also been estimated that 1 g of aerosolized botulinum toxin could potentially kill more than 1 million people [133,134].

**Pathogenesis**

Inhalational and foodborne exposures typically have a 12 to 36 hour incubation period, however symptoms have been reported within 6 hours and as late as 10 days following exposure [136]. Following exposure, the toxin enters the circulation, and the heavy chain of the toxin binds to the neuronal membrane on the presynaptic side of the neuromuscular junction. The toxin enters the neuronal cell, after which the light chain of the toxin cleaves the synaptic proteins that form the synaptic fusion complex. See Figure 130.14 for structure of botulinum toxin A. Disruption of the synaptic fusion complex prevents release of acetylcholine release into the synaptic cleft, leading to paralysis that may last for several months. Death from botulism is most often caused by respiratory muscle paralysis. The central nervous system is unaffected, because botulism toxin does not cross the blood–brain barrier. A prospective, observational cohort study of 91 botulism patients in Thailand showed that those individuals presenting with dyspnea; moderate-to-severe ptosis; and pupillary changes were likely to progress to respiratory failure, whereas a long incubation period before symptoms appeared was associated with a more favorable prognosis [137].
Botulinum neurotoxin-a is composed of an ~50 Kda light chain (red) linked by a single disulfide bond to the ~100 Kda heavy chain. The light chain functions as a zinc-dependent endopeptidase. The heavy chain has two components (blue and purple).

Treatment

The treatment of botulism includes supportive care, mechanical ventilation if necessary, and the administration of botulinum antitoxin. In severe cases, 2 to 8 weeks of ventilator support may be required prior to recovery. In an outbreak following an intentional release, the health care demands may rapidly overwhelm current capabilities, especially with regard to the availability of mechanical ventilators and critical care providers. There is a supply of mechanical ventilators in the Strategic National Stockpile (SNS) and in some state caches that can be deployed in the event of a mass casualty. The request must be coordinated via the local-state-national Incident Command System.

Rega et al. suggest an algorithm and triage tool to assess the severity of botulism cases that may be helpful during mass casualty situations [138,139]. Specific therapy for botulism involves the administration of botulinum antitoxin. Early suspicion of botulism and the prompt
administration of botulinum antitoxin can reduce nerve damage and disease severity. The goal of antitoxin therapy is to prevent further paralysis by neutralizing unbound botulinum toxin in the circulation. A new heptavalent botulinum antitoxin (HBAT) approved by the FDA replaced the former trivalent botulinum antitoxin in 2013 [140]. This heptavalent antitoxin contains equine-derived antibody to all seven botulinum toxins from A to G. If a case of botulism is suspected, prompt diagnosis is essential. If botulism is confirmed, the CDC will provide heptavalent antitoxin and detailed instructions for its intravenous administration (contact the local health department or if unavailable, the CDC at 770-488-7100) [133,141]. Additional doses of botulinum antitoxin will be needed when multiple cases of botulism occur after an intentional release. Following the initial administration of botulinum antitoxin, patients should be carefully assessed for refractory symptoms, such as rapidly progressing paralysis, severe airway obstruction, or overwhelming respiratory tract secretions, which may indicate the need for an additional dose.

Hypersensitivity reactions to botulinum antitoxin may occur. These include anaphylaxis, serum sickness, chills, fever, dyspnea, cutaneous erythema, and edema of the tongue. The incidence of hypersensitivity with the recommended one-vial dose is about 1%. A small dose can be given initially to screen for hypersensitivity, but this may be impractical in a mass casualty situation [133,134,142,143].

Human-derived anti–botulinum toxin immunoglobulin (BabyBIG-IV) is available as an orphan drug for the treatment of infant botulism, but it has not been tested for adults and is currently only available for infants under one year of age [144].

**Prophylaxis**

In the USA, a pentavalent botulinum toxoid vaccine was previously available from the CDC for the immunization of laboratory workers and military personnel at risk for botulinum toxin exposure, but this vaccine is no longer available as of 2011 owing to evidence of decreasing immunogenicity from the source strain. At the present time, there is no generally recommended prophylactic therapy for the prevention of botulism. High-risk exposures may receive HBAT on a case-by-case basis, in consultation with CDC [145].
RICIN

Ricin is a potent toxin belonging to the broad family of ribosome-inhibiting proteins and is easily extracted from seeds contained in the bean (Fig. 130.15) of the castor plant, *Ricinis communis* [146]. The castor plant, a native plant of Africa, is a common outdoor plant in warm climates and is also used for ornamental purposes. Castor bean seeds, castor oil, and the castor plant have been used for many centuries for their medicinal, lubricant, and decorative properties. Castor bean seeds contain high concentrations of ricin, and ingestion of as few as three seeds can be fatal. Ricin is an immunotoxin, allergen, and toxic enzyme that inhibits protein synthesis. As a result of its biochemical properties, ricin has antitumor effects and has undergone phase I and phase II clinical trials as a chemotherapeutic agent. Ricin can be inactivated by heating to 175°F for 10 minutes. It is odorless and tasteless and can be produced in liquid, crystalline, or dry powder forms. Both the liquid and powder forms have the potential to be aerosolized [72,146].

![Castor beans (Ricinus communis)](Figure_130.15)

Toxicology
Ricin is 66-kd globular protein consisting of two sulfide-linked polypeptide chains, A and B. The B-chain binds to the cell surface at galactose-containing sites and facilitates entry of the A-chain into the cell [147,148]. The A-chain then enters the cytosol of a cell; inactivates the 28S ribosomal subunits; inhibits protein synthesis; and causes cell death. Both the toxicity and the lethality of ricin depend on the exposure dose and the route of administration. In murine models, the LD50 and time of death are 3 to 5 µg per kg and 60 hours by inhalation, 5 µg per kg and 90 hours by intravenous injection, and 20 mg per kg and 85 hours by intragastric administration. The lethal doses of ricin for humans are estimated to be 5 to 10 µg per kg by inhalation and 1 to 10 µg per kg by injection [149]. On exposure to lethal doses of ricin by inhalation, rats develop a necrotizing tracheobronchitis and pneumonia with parenchymal inflammation and pulmonary edema [150]. In nonhuman primates, inhalation of ricin leads to death within 48 hours of exposure, and autopsy shows diffuse necrosis of airways, severe pulmonary edema, severe fibrinopurulent pneumonia, and mediastinal lymphadenitis [148].

**Ricin as an Agent of Bioterrorism**

The high toxicity, relative ease of production, ease of dissemination, and stability of ricin in ambient conditions make it a potential agent of bioterrorism. Ricin can be dispersed as an aerosol or as a contaminant of food and beverages for the purpose of causing multiple casualties. Ricin may be an ideal agent for small-scale bioterrorism attacks against high-value targets, because the large quantities needed for a large-scale attack are thought to be logistically difficult [146].

There have been several reports of the use or intended use of ricin in terrorist activities. In 1978, a Bulgarian diplomat named Georgi Markov, was killed in London by a ricin-containing pellet fired from an umbrella-based weapon [151,152] as shown in Figure 130.16. In January 2003, British authorities arrested 10 individuals from North Africa who were residing in a London apartment where ricin was found. In October 2003, ricin was identified in an envelope at a Greenville, South Carolina, post office [147]. In November 2003, an envelope addressed to the White House was reportedly intercepted by the Secret Service and was found to contain ricin. In February 2004, ricin was reportedly detected in the Dirksen Senate Office Building [146]. These events highlight the need for clinicians to be familiar with the recognition and management of ricin poisoning.
FIGURE 130.16 Diagram of “umbrella gun” clandestine weapon used to assassinate Bulgarian exile Georgi Markov in London in 1978. The poison projectile was propelled through the hollow tip by the pressure released from a carbon dioxide cartridge.

Ricin Toxicity in Humans

The pathologic changes and clinical symptoms caused by ricin exposure depend on the exposure dose and the route of exposure. The clinical effects of ricin for humans have been described following cases of castor seed ingestion and parenteral use in chemotherapeutic clinical trials. The clinical findings observed in animal models after the oral or parenteral administration of ricin appear to correlate with the clinical findings of humans exposed to oral or parenteral ricin. Human data on inhalational exposure to ricin is very limited. The findings from animals following inhalational exposure are presumed to be similar to those that would be experienced by humans following ricin inhalation. Leukocytosis appears to be a consistent finding, regardless of the route of exposure. Ricin toxicity by any route of exposure can produce a flu-like illness with fevers, myalgias, and arthralgias, as well as hallucinations and seizures [72].

Gastrointestinal Route

Compared to other routes of ricin exposure, the gastrointestinal route is the least toxic, and severity can vary based on the amount of ricin ingested. A review of 880 cases of mostly accidental castor seed
ingestions reported symptoms consisting of nausea, vomiting, and abdominal cramping within a few hours after ingestion, followed by diarrhea that may become bloody and lead to volume depletion, hypotension, severe electrolyte loss, tachypnea, tachycardia, and delirium with hallucinations. Case fatality rates of 1.5% were reported [146,147,153].

**Parenteral Route**

In cases of ricin toxicity produced by parenteral administration, pain at the site of injection, fatigue, malaise, headache, rigors, and fever were noted in the first 24 hours. Patients also showed local necrotic lymphadenopathy. Ricin, when used as a chemotherapeutic agent at a dose of 18 to 20 µg per kg, caused nausea, vomiting, myalgia, and fatigue. More serious adverse effects may include pulmonary edema, hypoalbuminemia, cardiac failure, hypotension, hypovolemic shock, acute hepatic and renal failure, gastrointestinal bleeding, thrombocytopenia, and bleeding diathesis [146,148].

**Inhalational Route**

Patients with inhalational exposure of ricin may develop symptoms within 3 to 24 hours. In nonhuman primate models, aerosolized ricin given in lethal doses produces severe diffuse, necrotizing bronchiolitis, massive alveolar edema with hemorrhage, and hemorrhagic tracheobronchial lymphadenitis, with death occurring in as little as 36 hours after exposure [154]. Sublethal exposure appears to produce a chronic pulmonary fibrosis in surviving animals [155]. The only information regarding human inhalational exposure is related to castor seed dust. Reported symptoms from dust inhalation include itchy eyes, nasal and bronchial congestion, urticaria, chest tightness, and bronchospasm, all suggestive of an allergic syndrome [146].

**Ricin as an Allergen**

Type I and IV hypersensitivity syndromes have been reported following dermal exposure to castor seeds and castor seed dust, including an anaphylactic-type reaction in a woman when a seed from her castor-bean necklace disintegrated in her fingers. The woman experienced rhinitis, sneezing, periorbital edema, and facial urticaria, requiring a subcutaneous injection of epinephrine [156]. Although the incidence of ricin-associated allergic reactions is unknown, they may be relatively frequent among exposed individuals because of the immunogenic properties of the ricin molecule.
Diagnosis

The diagnosis of ricin toxicity is challenging. The differential diagnosis includes exposure to staphylococcal enterotoxin, phosgene, oxides of nitrogen, and organohalides. If a bioterrorism attack is suspected, anthrax, plague, and tularemia should also be considered. Ricin intoxication by the inhalational route can be confirmed by ELISA analysis of nasal mucosal swabs taken within 24 hours of exposure. Specific ricin antigen testing or immunochemical staining of serum and respiratory secretions can also be performed [157]. Serum and respiratory samples may also be sent for PCR evaluation [158]. Because ricin is an immunogenic toxin, a significant increase of the anti-ricin antibody titer 2 weeks after exposure may also be helpful for confirming the diagnosis. It is recommended that acute and convalescent antibody titers be obtained for all individuals suspected of ricin intoxication. However, anti-ricin antibodies are rapidly metabolized and excreted, so the absence of a significant increase in titer does not exclude the diagnosis [147]. Urine testing for the ricin biomarker ricinine is under investigation [159,160].

Neutrophilic leukocytosis is usually present in peripheral blood. Pleural effusions and bilateral alveolar infiltrates, indicative of pulmonary edema, may be seen on chest radiographs. Arterial blood gases should be monitored to assess oxygenation, the adequacy of ventilation, and acid–base status. Myocardial ischemia, cardiac dysrhythmias, and cardiac conduction abnormalities may occur and should be evaluated through routine electrocardiography and echocardiography [146,148].

Treatment

The management of ricin intoxication is largely supportive, regardless of the route of exposure. All patients suspected of ricin intoxication should be decontaminated by removing all clothing and washing the skin with soap and water. Careful attention to fluid and electrolyte balance is essential, especially in patients with pulmonary edema. Vasopressors may be needed for the management of severe hypotension. If ricin ingestion has occurred, gastric lavage may be helpful for removing ricin from the gastrointestinal tract. If the patient is alert, activated charcoal can be given.

If inhalation is the route of exposure, effective airway management is essential. Bronchospasm should be treated with a nebulized bronchodilator. Patients with severe pulmonary edema will require intubation and mechanical ventilation. Oxygen should be administered at a concentration sufficient to keep the arterial oxygen tension (PaO₂) between 60 and 100 mm Hg. Myocardial infarction, myocardial ischemia,
cardiac dysrhythmias, and cardiac conduction abnormalities should be treated as appropriate. Mild allergic reactions can be treated with an antihistamine. Epinephrine should be given for anaphylaxis. A nonsteroidal anti-inflammatory drug can be given for arthralgias and myalgias [146].

There is no specific therapy for ricin. Chimeric and monoclonal antibodies directed against the A chain of ricin toxin have demonstrated benefits in animal models; however, human clinical data is presently lacking [161–163]. Some reported case series have described a positive experience with early plasma exchange of children following castor bean ingestion with symptoms of ricin intoxication [164,165]. Most patients with ricin intoxication should survive the acute effects if appropriate supportive care is given promptly after exposure. However, because the clinical effects of ricin intoxication are dose-related, individuals exposed to high concentrations may die from cardiopulmonary arrest in spite of the best supportive care [166].

Immunization

RiVax/Alum (Soliginex, Princeton, New Jersey) and RVEc (USAMRIID, Fort Detrick, Maryland) are recombinant inactivated ricin A-chain toxoid vaccines that have been shown to be immunogenic and safe in small phase 1 human trials [167,168]. These vaccines appear to be comparably immunogenic when compared in a murine model [169]. The use of these agents in cases of a human outbreak or attack remains to be determined.

Table 130.13 provides a useful summary table of biologic agents, clinical features, and initial treatment.

ICU DESIGN, ORGANIZATION, OPERATION, AND OUTCOME MEASURES
NEIL A. HALPERN
INTRODUCTION

In 2010, there were approximately 6,100 intensive care units (ICUs) with over 104,000 beds in the 3,100 acute care hospitals in the USA [1]. Periodically, these ICUs need to be renovated or new ICUs built [2]. Thus, hospital-based intensivist administrators at some point in their careers may be asked to participate in designing new or renovating existing ICUs. For simplicity of presentation, we have divided this chapter into five sections: the ICU design process; the ICU patient room; central clinical, visitor and staff support, and administrative areas; ICU informatics; and future trends. Although we classify these areas separately, they are indeed interrelated.
THE ICU DESIGN PROCESS

Health care and design are complex processes that must accommodate and address continuously evolving guidelines and regulatory standards [3]. Several core principles should guide ICU-specific design [4]. First, an ICU is a semiautonomous mini-hospital. Second, new or renovated ICU locations should be harmonized with other ICUs and hospital support services. Third, the design must balance innovation and functionality, space and physical limitations, costs, and security and healing. Fourth, ICU design should account for long-term functionality, because the ICU design must last a decade or more. Finally, ICU design should embrace the growing field of Evidence-Based Design (EBD) [3,5–7]. In EBD, design decisions about the built environment are predicated upon credible research to achieve the best possible results. Thus, facility design and positive health care outcomes are linked to produce workforce safety, satisfaction, productivity, cost savings, and energy efficiency [2,3,8–11].

The design should also accommodate evolving perspectives for the number of ICU beds per unit and differences between critical care delivery models for large and small hospitals. The average number of ICU beds per unit has increased between 1993 and 2012. Adult ICUs are now bigger by almost six beds, or 29% [12]. Additionally, there are usually a high percentage of hospital beds dedicated to critical care in larger than smaller hospitals [13]. Moreover, within the large academic medical centers there are multiple specialty ICUs (i.e., medical, surgical, coronary care, cardiothoracic, neurosurgical, pediatric, and neonatal), whereas, one large multipurpose adult ICU may suffice in smaller community hospitals. Additionally in large academic Emergency Departments (ED), an ICU may be incorporated into the ED.

ICU Design Team

ICU design can succeed only if common goals for design, space, purpose, and funding are shared between the critical care medicine team and the hospital administration [4]. Because critical care is multidisciplinary, the ICU design process benefits from being inclusive and collaborative [3,4,8]. Therefore, the ICU design team should include a variety of disciplines including hospital administration; the ICU clinical team (physicians, nurses, and pharmacists); allied health care support (infection control specialists, respiratory therapy, nutrition support, care coordination, and social work); and the technical groups (architects, engineers, equipment, and informatics). Ideally, architects and engineers with a prior track record of successful ICU design experience should be
engaged. It is also important to include end users (patient and family representatives), because these groups can offer unique insights [9].

Initial Vision & Benchmarking

The 40,000 foot perspective articulating the vision for the new ICU precedes design specific deliberations [4,14]. This perspective includes the location of the unit, the number of beds, the apportionment of space between patient and supportive areas, and the logistics of unit function (centralized or decentralized). The vision for the new ICU should reflect the desired atmosphere and approach to patient and family care, workflow, technology, and the ICU’s physical and logistical relationships with the remainder of the hospital. Developing the vision may be helped by benchmarking their ideas with visits to select ICUs and meeting with their staffs.

Design Guidelines & Regulatory Standards

The design process should be initiated by utilizing existing evidence-based guidelines, recommendations and expert opinions to gather core knowledge of ICU design [4,5,14–19]. An early understanding and integration of ICU guidelines and standards allows the team to develop the broad strokes of a functional program and a roadmap which will define the character, services, scope, and space requirements in sufficient detail for subsequent design.

Two primary sources include the Guidelines for Design and Construction of Hospitals and Outpatient Facilities, published by the Facility Guidelines Institute (FGI) [19] and The Guidelines for Intensive Care Unit Design published by the Society of Critical Care Medicine (SCCM) [15]. The FGI and SCCM guidelines are periodically updated. FGI focuses on minimum standards for design and construction (space; risk assessment; architectural detail; surface and furnishing needs; and engineering). The SCCM guidelines describe universal functions that should be accommodated in the modern ICU. Interestingly, both codes and guidelines have expanded their recommendations to include the social, psychologic, and/or cultural aspects of facility performance, thus responding to the need for a more comprehensive approach to health facility design [2]. SCCM also maintains a digest of the ICU design award winners and includes architectural design drawings, pictures, and videos of outstanding ICUs from throughout the world [20].
Design Timeline & Mock-Ups

The ICU design process may take several years from initial design vision to initial occupancy [4]. Design committee meetings that are regularly scheduled and provide continuously updated schematics and computerized renderings of the various architectural concepts generated by the team speed the process along. Full-scale prototypes or “mock-ups” of the patient rooms are now standard practice and allow for an experiential rather than an observational understanding. Moreover, mock-ups permit staff to gain a sense of how the space and size of the room will accommodate patient care and workflow of the design. The mock-ups can range from simple tape on the floor to indicate room outlines and components, to the use of cardboard walls and spaces with devices and finishings [8,21].

Renovation versus New Construction

Both renovations and new construction are heavily regulated by building codes. Renovations are mandated to update existing space as much as possible to current building codes. In contrast, in new construction, the design begins with a clean slate and is built to current code. Renovations of existing ICUs are usually limited in scope and may range from a cosmetic upgrade to a total overhaul. Renovations are often more complicated than new build because of the restrictions of building in an older space (i.e., existing floor-to-ceiling heights; structural depths; and presence of elevators and staircases). Renovations also need to include planned phasing in order to minimize disruption to existing patient services. Phasing plans should include considerations of noise and vibration control that result from construction activities [19].

Occupancy Phase and Post-Occupancy Evaluation

Preoccupancy preparations including moving day simulations can diminish moving day anxiety and mistakes. Non-ICU staff and the family members of current ICU patients should be made aware of the moving date in order to minimize their angst.

A post-occupancy evaluation (POE) process has been developed to identify major issues and unanticipated problems and plan for short- and long-term fixes. POEs tend to focus on end-user impressions after occupying the facility, but not necessarily on clinical performance measures [2]. When implemented in health care design, research findings demonstrate that POEs can positively impact patient and visitor experiences and satisfaction; create supportive work environments for staff and caregivers; and help achieve organizational objectives [22].
THE ICU PATIENT ROOM

ICU Layout

Before discussing the patient room, we must think about the ICU layout, arguably the most important design feature that affects all aspects of intensive care services including patient privacy; comfort and safety; staff working conditions; throughput; logistical support; and family integration [23, 24]. Layout determines the location of different spaces and/or functions within an ICU, the relationship of internal and external spaces, and how their functions relate. Within the physical limitations of the space, designers have applied various types and combinations of layouts (Fig. 131.1) to solve throughput and circulation challenges for patients, staff and visitors, clean and used supplies and equipment [12].
FIGURE 131.1 ICU configurations: rectangular (A), circular (B), triangular (C), and square (D). The “racetrack” (A) with patient beds around the perimeter and nursing stations and supportive services in the CA is most common in current ICUs. Corridors cut through the central areas to facilitate staff movement. CA, center area; ICU, intensive care unit.

The ICU layout choices are usually dictated by the physical configuration of the facility and the location of fixed components (i.e., windows, staircases, elevators, and plumbing). Layout decisions may also be guided by considerations that address safety versus efficiency; support versus function; and revenue-generation (patient rooms) versus logistical spaces [12]. The racetrack (patient beds around the perimeter with services in the center and a loop corridor space in between) appears to be the most dominant unit layout among award-winning adult ICUs [23].

ICU Patient Room
The central point of the ICU experience is the patient room. Guidelines advise single bed rather than multibed rooms in order to enhance patient safety and privacy. Each room should be equipped to function as an autonomous area with the necessary space for procedures and associated staff. Each patient room should offer a healing environment; support infection prevention measures; and have access to outdoor views through windows. Concomitantly, the rooms should be fully interwoven into the ICU and hospital workflow and social fabric.

Patient Room Standardization

Ideally, all ICU patients’ rooms should be standardized for layout. The patient rooms can be designed identically (same-handed) or as mirror images of each other. Room standardization may save design and construction time and costs and improve patient safety. Importantly, patient room standardization allows staff to move in and out of each room efficiently because the staff members always know where devices are installed and supplies stored and placed. Layout standardization is commonly restricted by plumbing conduits for bathrooms.

Additionally, the rooms should be standardized for size. At a baseline, minimal patient room size requirements are guided by the FGI and state-based rules. However, the consistency of space availability depends upon the existing physical layout; this is particularly limiting in ICU renovations. Additionally, some care environments, notably surgical specialty ICUs, may purposefully build a few rooms larger than others as large spaces are needed for some supportive technologies. The build of at least one large bariatric room per ICU should be considered as obesity rates are increasing, reflecting a trend in the general population.

Patient Room Zones

ICU patient rooms can be subdivided, physically or virtually, into four zones: patient, caregiver (work), family (visitor), and entry way. The room’s focal point is the patient bed. Optimally, all medical equipment should be installed on a medical utility distribution system; this approach clears the floor and facilitates ready access to the patient by visitors and staff. The caregiver zone includes work areas and space for medication preparation and procedures, as well as computers, displays, and storage areas. The design of the caregiver physical environment should not hinder the interplay between critically ill patients and their families. The family zone should incorporate comfortable chairs; power outlets; wireless access; and, if space permits, a long-term visiting alcove with a chair–sofa–bed, table, light, sink, locker, and refrigerator. The entry way for each patient room may open
directly onto the hallway or be set back from the hallway (Fig. 131.3). Opening directly to the hall provides the largest possible patient room; however, setting the room back may provide a staging area that incorporates a decentralized workstation; handwashing system; storage space; coat hangers; and identification and informational display systems. A hybrid design that incorporates both direct hallway access and a setback may provide the best of both worlds (Fig. 131.3C).

**FIGURE 131.2** The ICU patient room is divided into four zones: patient (1), caregiver (2), family (bedside—3A or long term—3B) and entryway (4). This figure also demonstrates a nurse server with bidirectional access, work area, supply space, mobile articulating arms (booms), bathroom, webcam, Wi-Fi transmitter, and a workstation and a staging area immediately outside the room. ICU, intensive care unit.
FIGURE 131.3 Patient rooms may open directly into the hallway without any workstations (WS) (A) or with a shared workstation for the two rooms (B). Alternatively, the rooms can be set back to provide a
staging area (C—left room—full staging or right room—partial or hybrid staging) in front of each room with one workstation per room.

**Medical Utility Distribution Systems**

The primary decision that guides the room’s utilization involves the selection of the medical utility distribution systems [29]. This system brings the hospital’s supportive infrastructure (medical gases, vacuum, plumbing, electrical and data jacks) to the patient and provides the venue for installing medical devices (physiologic monitors, mechanical ventilators, infusion pumps), and communications and entertainment systems. The choices are divided between fixed headwalls or floor mounted columns versus mobile articulating columns (booms) mounted to the ceilings or walls (Fig. 131.4). The stationary systems are less expensive than the mobile systems; however, the mobile booms offer greater flexibility, patient access and bed movement.
A. Stationary headboard

B. Stationary columns

C. Mobile articulating arms (booms)
Utilities and devices are mounted on a stationary headboard (A), stationary (left) or rotating (right) columns (B), or mobile articulating columns (booms) (C). The booms can be attached to the walls or ceiling, at any corner of the bed and swivel and move horizontally or vertically.

**Bedside Medical Technologies**

Core ICU room medical devices ideally include the ICU bed; physiologic monitor; mechanical ventilator; infusion and feeding pumps; pneumatic compression devices; patient lift; computers; chairs for the patient and visitors; overbed tables, laboratory-specimen label printer; nurse-call intercom station; webcam; entertainment system; storage areas; and waste disposal bins. The design team should also address point-of-care testing (POCT) and ultrasonography and whether these devices should be placed in each room or positioned centrally.

**Patient Room Logistics and Waste Management Systems**

Adequate storage spaces for supplies, medications, linens, and waste management systems should be incorporated into each patient room. Storage is achieved through a mix of permanently based secured and nonsecured drawers and cabinets, and/or mobile carts. Nurse servers (cabinets with bidirectional and secure access from both outside and inside the room) may be a good solution (Fig. 131.2) to improve privacy and infection control by stocking the room from the outside.

ICU patient rooms must now have direct access to separate enclosed bathrooms [19]. Therefore, the design must determine the optimal bathroom location (i.e., front of room, back of room, or front and back of adjacent rooms) (Fig. 131.5). These decisions will probably be based upon the availability of plumbing; nevertheless the impact on patient visualization, window availability or workflow is quite important. Patient bathrooms should have either sanitizers to clean reusable bedpans or macerators to destroy single-use bed pans.
The ICU patient room bathroom (WC) can be located in front of the room (A) ("inboard"), back of room ("outboard") (B) and in the front of one room and the back of the adjacent room ("nested") (C). The impact on patient visualization from the hallway, window availability and workflow should be considered by the design team.
ICU, intensive care unit.

Front of ICU Room and Decentralized Workstations

The front of the ICU patient room is the interface of the room with the ICU hallway and ICU central areas. This space controls room entry; patient privacy; sound transmission; control of infection; and impedance of smoke, and allows for patient observation and monitoring. Options for front-of-room privacy include curtains; clear glass doors and curtains; and glass doors with integrated privacy solutions (manually or electronically controlled integral blinds or electronic glass [Liquid Crystal Devices (LCD) or e-glass]). Curtains are more economical to install than glass systems; however, the curtains are not efficacious controllers of sound, infectious agents, or smoke. Glass systems are also easier to clean.

The front of each room also provides a ready location for patient observation and monitoring through the incorporation of a clinical workstation (decentralized). These workstations facilitate the deployment of staff close to the patient [6]. Such workstations are generally designed as one per room or one per two rooms depending on space considerations and room build (Fig. 131.3B and C). The workstations should have ready digital access to all bedside physiologic data (mirrored on displays or web-based) and to the electronic medical record.

The Room as a Healing Environment

Although the exact design features that transform ICUs into healing environments are not definitively identified, it is well known that the physical environment affects the physiology, psychology, and social behaviors of all those who experience it [7,30]. Thus, it makes good sense that the patient room environment promote healing and serenity by addressing sound, light, temperature, visuals, and entertainment aspects [31,32].

Sound control positively influences patient outcomes by lowering physiologic stress, sleep disturbance, and feelings of fear [33,34]. The highest noise levels in the ICU have been shown to be related to staff conversation and the use of advanced technical equipment. Acoustic control within the ICU is generally achieved through the integration of sound minimizers (sound-absorbent finishings and ceiling tiles, acoustic baffling in the walls, soundproofed windows, and sound attenuators in the HVAC system), patient level sound mitigaters (sound cancelling headphones or sound masking) and systems that control bedside alarm volume and communication broadcasts.

Natural light is essential to the well-being of patients and staff. Thus, ICU patient rooms are now all required to have windows [15,19,32]. However, the associated glare should be controlled with antiglare glass as
well as sunlight reducing shades, preferably with electronic controllers. The room itself should have multiple lighting arrangements to accommodate patient and staff needs, including multifunction LED lights (with low energy or heat producing bulbs) and procedure lighting.

Artwork can be mounted on the ICU walls, embedded in privacy curtains and ceiling tiles, electronically projected on video displays, or integrated into monitors or television/computers. Entertainment may also be provided through visor-based video displays. A “low-tech” white board should also be available in each room for the display of positive messages, get-well cards, and family pictures.

Electronic and computer-based integration of the environmental (light, shades, temperature, and artwork) and entertainment systems into remote handsets (pillow speaker) or wall based computer switches facilitates efficient patient and staff centered control of the room. Environmental profiles can then be tailored to day and night, procedures or no procedures, and individual patient preferences. Multiparameter sensors that monitor temperature, humidity, light, sound and provide alerts for uncomfortable environmental circumstances also help track and maintain the healing environment.
CENTRAL CLINICAL, VISITOR AND STAFF, AND ADMINISTRATIVE SUPPORT AREAS

The central stations and corridors unite all the patient rooms as well as other supportive areas and can create unit cohesiveness. The goals of all central areas are to support bedside care, offer a welcoming and warm atmosphere, and provide access to logistical support areas. Design of these areas is governed by the hospital’s and ICU’s approaches to centralized or decentralized care and logistics and space availability.

Central Care Stations

The composition of the central care stations includes greeting desks; areas for quiet work and conferencing; as well as offices and restrooms. Technologies usually include nurse-call communication stations; telephones; communications boards; computers; high-definition image review stations; laboratory-specimen label printers; pneumatic tube stations; nourishment stations; emergency alerts; and cut-off switches for ICU utilities.

In a small ICU, one centrally located station may suffice; in contrast, multiple central stations may be needed for a large ICU with several bed pods. The layout of these areas is primarily affected by the bed configurations (Fig. 131.1). Optimally, unobstructed views of the ICU beds should be available from the central care stations. Studies have suggested that decreased visibility may negatively affect clinical outcomes for severely ill patients assigned to rooms that are poorly visualized by staff [35,36]. In reality, unimpeded views are commonly precluded by the ICU layout. However, visibility from central areas can be enhanced electronically through the use of webcams in each room and central displays of bedside devices.

Corridors

ICU corridors provide pathways for transit and promote physical and social unity. However, physical barriers (staircases, elevators, supportive conduits, and closets) can limit optimal corridor design. If possible, separate hallways should be designated for patients or supplies to enhance patient privacy and decrease visitor distractions. Corridor design may also have to support access to permanent imaging and procedural suites as well as passageways for large mobile imaging technologies (i.e., mobile CT scanners).
Corridors are fixed spaces that provide access to permanent rooms; however, the corridor design should be more expansive and include access to transport systems (i.e., elevators and helicopters) and the design plan can also address the transport systems themselves. For example, in a new build, transport elevators should not only be large enough to accommodate the patient bed, staff, and other care devices, but should be equipped with utility panels that provide power, oxygen and suction. The outdoor passageways, or pre- or post-helipad areas should likewise include supportive utilities.

The corridors through their finishings, artwork, sound control, and lighting set the emotional tone for the ICU. These considerations are relevant, because hallways are commonly used to conduct rounds, impromptu clinical consultations, and family meetings. Moreover, the corridors may also impact the patient psyche as patients frequently walk through the corridors within the context of early mobility programs [37].

ICU Storage Spaces, Supplies, and Medical Devices

Right-sizing and properly positioning the storage areas (central and bedside) requires a sound understanding of the logistical approaches (centralized and/or decentralized) that the hospital and ICU deploy. Right-sizing the storage space also requires correct assumptions of ICU supply utilization of consumables. Outfitted storage units and expensive supplies and equipment with electronic tags promote inventory management and permit the use of real-time locating systems/solutions (RTLS) [38].

Storage spaces may include traditional supply rooms (with stationary or track-based shelving; closed supply cabinets; or rolling exchange carts) as well as alcoves along the ICU hallways. Storage spaces should be accessible to transport or cargo elevators and be fairly close to the patient care areas. Central storage spaces must also be able to handle and charge supplementary medical devices (i.e., infusion pumps; ventilators; and specialty monitoring or imaging devices).

Pharmacy

Hospitals may have centralized or decentralized pharmacy and medication distribution systems and staffing models. Therefore, ICU pharmacy systems must be coordinated with the hospital’s pharmacy and ICU bedsides. Options include a fully equipped satellite ICU pharmacy versus a pharmacy area with minimal resources. Both alternatives
commonly utilize decentralized self-contained and secure automated medication disposing units. Medications may also be stored in secured cabinets at the ICU bedside.

ICU Laboratory and POCT

Many ICUs utilize laboratory testing from a centralized lab. However, if point-of-care testing (POCT) will be incorporated, the design must accommodate POCT systems.

POCT focuses primarily on whole blood analyses using either large devices placed in defined ICU locations (ICU stat laboratory or central station) or on carts, or smaller devices amenable for positioning at each ICU bedside [39]. A combination of POCT modalities and locations may be used depending on the ICU workflow, required testing, and available space and resources. Pneumatic tube stations are still required to transport specimens to laboratories outside the ICU area as POCT is currently not a complete replacement for the central laboratory.

Infection Control and Prevention

Effective infection control requires an ICU culture that is responsive to infection deterrence and an ICU infrastructure designed to support infection prevention measures. Core infrastructure elements include systems that provide clean air and water, and waste sequestration and elimination. Nonporous, well-sealed, and easy-to-clean surfaces and finishings throughout the patient rooms; and ubiquitous, visible, and accessible hand sanitizers and fluid dispensers are critical to infection control. Advanced modalities include electronic handwashing surveillance; self-cleaning copper or silver surfaces; surface surveillance monitors; and the use of environmental decontamination systems (i.e., ultraviolet light, hydrogen peroxide dispersion, and continuous air disinfection) [17].

Unfortunately, even in the setting of optimal infection control design, serious infections will likely remain an ICU problem. Therefore, ICUs may have to maintain duplicate devices to be used primarily with highly infectious patients (i.e., bronchoscopy towers and disposable bronchoscopes) and may even have to develop “super” isolation zones that group highly infectious patients together with designated ICU traffic patterns.

Visitor and Staff Support

It is well recognized that family support is a significant factor in patient recovery. Concomitantly, family members and visitors can become emotionally depleted when their loved one is an ICU patient. With these
factors in mind, it is important to build family “waiting” areas to promote visitor wellness [40,41].

ICU visitors need a healing environment in close proximity to the ICU to recharge between visits with their loved ones. Soft lighting, warm colors, large windows, nature-themed artwork (either real or electronic), and quiet background entertainment set a serene tone. Privacy should be provided using small groups of comfortable chairs that are separated by dividers. Informatics support may include wireless Internet access; computers; and smartphone charging stations. Nourishment areas as well as bathrooms, lockers, and coat hangers should be the norm. Long-term sleeping accommodations, if possible, provide a space for visitors who prefer to remain nearby. The inclusion of consultation rooms and social work offices near the waiting areas and the addition of respite areas for ICU visitors within the ICU hallways also helps promote family meetings and social and emotional support.

**Areas for Staff Respite and Meetings**

Similar to the ICU visitors, ICU clinicians regularly face extreme stress. Therefore, the ICU design must address the impact of staff spaces. Well-designed staff lounges (break rooms) and on-call suites located within the ICU provide a private place adjacent to patient care areas for staff relaxation. The lounges should be tastefully decorated with outside lighting; comfortable seating; tables and access to computers; ICU communications; and entertainment. Bathrooms; changing areas; lockers and scrub dispensers; napping alcoves; and nourishing stations complete the lounge furnishings. In ICUs that maintain 24/7 clinician availability, sleeping accommodations (on-call suites) with bathrooms and showers should also be provided.

**Conference Rooms**

Staff meetings, educational programs, and family meetings are sustained through the construction of multipurpose conference rooms within the ICU environment. The seating capacities of these rooms should be based upon predicted usage. Furnishings should include comfortable seating; conference tables with built-in informatics access; audiovisual video systems; wireless access; smart boards; electronic attendance and scheduling systems; food preparation; and storage areas.

**Staff Communications**

Telephones, smart phones, nurse-call intercom systems, pagers, and bidirectional transmitters are integral to the ICU communications environment. These devices may all be integrated into one platform (i.e.,
within a nurse call system, a primary communication platform, or an alarm system). Functionalities include point-to-point and global messaging, telephone and alarm communications, and real-time locating of staff. Even in these advanced settings, land-line telephones and overhead speakers continue to be of value in providing reliable ICU communications. Panic buttons can be installed in commonly used work areas in order to ensure staff safety or incorporated into communications gear.

**Signage and Wayfinding**

In addition to a well-designed ICU layout, good signage is necessary for efficient wayfinding. Directional signs should be clear in their message and easily visible. Destination signs should identify each room. Signs at the ICU entrance provide information about the ICU and can include the ICU designation (i.e., surgical ICU), management names (i.e., ICU director and nurse leader), and visiting hours.

**Security and Fire Safety**

Security and fire safety is crucial in the ICU setting. Electronic identification card–coded access should be used for staff at all secure doorways. The ICU entrance optimally should be staffed by dedicated clerks. However, staffing limitations commonly preclude full-time greeters; therefore, other systems for visitor identification (i.e., closed-circuit televisions with electronic buzzers) should be installed at ICU entrances.

Beyond the basic fire safety devices (smoke detectors, automated sprinklers, fire extinguishers) and fire and smoke alerting systems (fire alarm pull-stations, sound or light alerts and overhead speakers), four design elements help ensure the safety of the ICU in the settings of fire or smoke. The first involves selection of products and furnishings with a low fire load and minimal release of heat and toxic smoke. The second addresses the construct of compartments that are fire and smoke-rated. The third is the use of protective technologies within the HVAC systems to prevent the spread of smoke and other products of combustion from one area to another. The last is the integration of experienced fire safety officers into the ICU design process [17].
ADVANCED INFORMATICS

The deployment of advanced informatics into an ICU, thus creating a “smart” ICU, certainly provides enormous positive potential for unit operations [18]. However, designing the informatics infrastructure requires a different skill set than the standard build and therefore, requires a team trained in the intricacies of informatics. The primary objective of advanced informatics systems should be to electronically integrate the patient and staff with all aspects of care. The second goal is to transform patient-related data into actionable information. The biggest challenges in this endeavour are harmonizing the technologies of multiple vendors into an operational platform that will meet the ICU needs and be fully synchronized with hospital informatics systems.

Building the Smart ICU

The smart ICU infrastructure requires a connectivity envelope (Fig. 131.6) around the patient. This envelope encompasses the patient, medical devices, health care staff, as well as pharmacologic and other care elements [18]. The core components include a robust wired and wireless infrastructure at each bedside, connectivity hardware within the patient room to connect and communicate with data sources, identification tags on data sources for tracking purposes, transmitters on medical devices to transmit their data, and middleware (the software that connects, provides interoperability and other applications between medical devices and the hospital’s operating systems) on hospital and ICU networks.
The Food and Drug Administration (FDA) classifies middleware as either Class 1 medical device data systems (MDDS) or Class 2 devices. MDDS devices maintain data storage and data transfer, and also convert proprietary device languages into interoperability-standardized formats. Class 2 applications additionally offer active patient monitoring and alarms and therefore, receive enhanced FDA scrutiny. Applications inherent in ICU middleware include transforming hospital and ICU data and alarms into actionable information, managing devices, applying RTLS, creating smart displays, providing decision support, and facilitating telemedicine programs. The hospital’s bed management system should be interfaced with the ICU middleware to automatically populate the ICU middleware with the ICU census. ICU middleware should also be compliant with hospital privacy protocols and lastly should have off-site backup systems.

**Advanced ICU Informatics Concepts**

Integral to advanced informatics are four concepts. The first is the linkage or association (location or patient centric) of the patient with the medical devices and the data generated by those devices (Fig. 131.6). The location-centric approach uses the patient’s location for data linkage, whereas the
patient-centric approach uses the patient’s unique medical identification number. The location-centric solution is simpler to implement than the patient-centric method; however, the latter solution always attaches the data to the patient, regardless of patient movement within the hospital. The second concept is the application of interoperability between systems. Interoperability aligns the proprietary data output languages of the medical devices with the recipient middleware. Interoperability allows the data generated by one device to be clearly understood by the receiving middleware. Without interoperability, the data produced by the medical device may not be integrated into the electronic medical record even though the devices are connected to the hospital network. The third concept addresses time synchronization between all medical devices, middleware and the hospital network. Time synchronization helps create a correctly time-stamped medical record for all data from all sources. The fourth concept equates medical devices with informatics platforms. All new medical devices are actually advanced computers and consistently changing software versions and occasional hardware upgrades. Thus, informatics purchases should be carefully assessed in simulation laboratories to best evaluate their proposed informatics capabilities. As for all informatics platforms, the costs of annual software upgrades and licensing agreements should be prospectively budgeted.

Alarm Systems

Alarm middleware transforms select alarms from medical devices into relevant and actionable information. Such middleware can deliver the alarms to designated providers in real-time in a variety of formats and displays. The most sophisticated of these systems can process and create customized alarms based upon combinations of alarms and other data (i.e., multiple physiologic and laboratory values) as well as create personalized patient alarms from streaming raw device data.

Virtual Device Communities

Stand-alone medical devices (i.e., mechanical ventilators) are commonly linked to an individual patient. Alternatively, all ventilators can be linked together through device middleware to generate a “virtual” device community. In this setting, one can view all ventilators (settings, data and alarms) in the facility simultaneously. Additionally, such systems provide data storage, alarm transmission, report generation, remote viewing capabilities, and a portal for software upgrades and device monitoring by the vendor.

Real-Time Locating Systems
RTLS middleware offers solutions to improve workflow efficiencies of all assets (staff, patients, equipment, consumables, and patient rooms) [38]. RTLS to date are used primarily to locate tagged devices (mobile asset tracking) and to provide notification if devices leave designated areas. RTLS can also track the usage of consumable-tagged supplies to monitor inventory and directly link supplies to patient utilization. Within the ICU, RTLS can be integrated into nurse call systems and used to monitor patient and staff movements, compliance with hand washing protocols, and the environment.

**Data Integration, Smart Displays, and Decision Support**

Middleware applications can integrate, transmit and display data from a host of data sources (i.e., EMR, bedside devices, bed management systems, RTLS, imaging servers, webcams, and decision support systems). Such data can then be displayed imaginatively in a variety of formats and devices. Other middleware systems provide real-time intelligent algorithms and decisions support to monitor and sniff (automated systems that search for preselected data elements) for clinical abnormalities that may not be detected by traditional monitoring systems.

**Telemedicine**

The ICU informatics design also provides the framework for telemedicine through the use of interfaces and bidirectional communications systems. These technologies transmit data, clinician orders, video and voice between the various ICU areas and the hospitals’ telemedicine support center. This allows the remote intensivists to identify signals of potential physiologic instability and communicate actionable intelligence to bedside caregivers. Such solutions are applicable whether the hospital outsources telemedicine to a third party at either an on- or off-site location, or internally to the hospital’s own telemedicine team. Alternatively, the hospital can install web-based middleware that interfaces with hospital systems and allows dedicated members of the critical care team to respond in real time to integrated information from hospital (laboratory, imaging studies, and reports from consultants) and ICU systems using various handheld platforms.
THE FUTURE OF ICU DESIGN

ICU design of the future will likely incorporate the cost-savings possibilities derived from evolving trends in critical care models. Thus, larger units with more ICU beds per unit may become the norm, as hospitals look for the efficiencies thought to be associated with building and managing units with economies of scale. Larger units may also become multispecialty units, subdivided into smaller groupings of beds supported by a balance of centralized and decentralized workstations, and logistical support areas.

Standardization may become the norm for ICU design with identical vendor-based technologies and systems in multiple units within one medical center. ICUs will likely be located in close proximity to each other especially in new facilities. Core areas adjacent to or within these units may include shared multiuse diagnostic and treatment technologies; administrative, educational, and/or research spaces; and family areas. Patient- and family-centered care will be encouraged through the build of larger patient rooms that are better able to accommodate family and required bathroom space. Ceiling mounted life support systems will replace fixed models and wirelessly integrated devices will allow for improved documentation, communication, and patient access. Segregation of public/visitor and patient/support circulation types will be pursued.
CONCLUSION

The goal of intensive care is to provide the highest-quality treatment in order to achieve the best outcomes for critically ill patients. Research supporting the impact of the built environment has exerted a strong influence on multidisciplinary design teams, as they seek solutions to maximize operational efficiency and create supportive healing environments for patients, families, and clinical staff. The ICU is an ever-changing and rapidly advancing environment. Future ICU designs will require planning for long-term flexibility by incorporating design decisions that accommodate changing care practices and information technology.

INTRODUCTION

Organization is the act of assembling elements into an orderly, functional whole. Management is the ongoing revision and renovation of that careful assembly to cope with change. The notion of organization is well known to intensive care unit (ICU) division and service chiefs and directors who have hospital or departmental responsibilities to deliver critical care services. The concept of “bedside management” is familiar to clinicians who titrate vasopressors or adjust ventilator settings. ICU management is itself a form of titration and continuous adjustment that addresses creating and implementing policies and procedures, arranging service and interprofessional rounds, preparing budgets, and complying with regulations. The successful ICU director must also have both organizational skills and leadership capabilities to relate to the rest of the hospital and innovate and facilitate change. Creativity is important in these processes, but perseverance may be the most essential character trait because of the many ways a typical organization will resist change. Table 132.1 outlines the strategic (leadership) and tactical (managerial) responsibilities of an ICU director.

Knowing how to navigate the obvious and the subtle impediments to change is a key skill for ICU leaders, beginning with the nurse manager and physician medical director and extending through a hospital’s or system’s leadership hierarchy. The contemporary trend toward increasing requests for ICU admissions and shrinking reimbursement for services rendered will require ever more sophisticated organization and experienced ICU managers. Although organizational reporting has historically been based on traditional departmental structure (e.g., medicine, surgery, and pediatrics), there is an emerging trend in North America toward Critical Care Organizations (CCOs) [1] that supervise and govern the delivery of critical care services across departments and increasingly across entities of a health delivery network.

The conceptual frameworks [2] and business skills for successful ICU leadership must be acquired, whether in business school or on the job [3].
Important characteristics of leaders include self-awareness, self-regulation, motivation, empathy, and social skills [4]. The American Association for Physician Leadership is an organization that provides guidance on how to prepare for and succeed in medical management [5] ranging from journals to seminars to master’s degree preparation. A formal Masters of Business Administration program will typically include courses on accounting, data analysis, ethics, financial analysis, human resource management, information systems, marketing, production/operation management, organizational behavior, organizational planning and strategy, quality improvement (QI), teambuilding, and leadership. Many physician practice groups now offer training and business career development. This chapter will focus on the most relevant subset of ICU organization patterns, human resource issues, the roles of the ICU director, methods for monitoring clinical ICU care, and ancillary management issues.
ICU ORGANIZATION: GOVERNANCE

ICUs were initially developed to facilitate nursing efficiency by permitting higher nurse to patient ratios in a geographically constrained area and also to accommodate then-unfamiliar technologies such as telemetry and mechanical ventilation. Early units were typically converted contiguous double-bed patient rooms or hospital wards, with purpose-built facilities becoming more common after the 1960s. Many hospitals organized specialty-specific units (e.g., Medical ICU, Surgical ICU, and Pediatric ICU) governed as critical care services or divisions within existing departments of medicine, surgery, or pediatrics. Larger and academic medical centers additionally developed a variety of highly specialized units (e.g., trauma, burn, neurosurgery, and cardiac surgery) reporting through existing departments or subspecialty service lines. Smaller hospitals might have a single shared unit caring for all critically ill patients, but separately directed by medical, surgical, cardiology, or pediatric services. Although some hospitals created hospital-wide critical care practice committees to coordinate bed management, purchasing, common protocols, or “Code Blue” responses, units were more often silos within specialty service lines rather than highly coordinated.

The concept of a “CCO” within a hospital is a more recent development. With the consolidation of individual hospitals into integrated health care delivery networks, enterprise-wide committees seek to standardize practices. Many institutions have transitioned from traditional academic departments (e.g., medicine, surgery, and pediatrics) to service lines, centers, or institutes (e.g., neurosciences, heart and vascular, and digestive diseases) that employ physicians and other providers from multiple departments and thus require matrix reporting arrangements. Critical care may be structured as a support service for the entire organization (e.g., one or more multidisciplinary ICUs caring for both medical and surgical patients) or embedded within a service line (e.g., a Neuro ICU within neurosciences, a cardiac care unit within heart and vascular). Either way, system-wide coordination is essential on matters of triage, training of nurses and support personnel, protocols and order sets in the electronic medical record (EMR), standardization of equipment, equipment and operating budgets, recruitment, quality assurance, education, and research.

A number of operational models exist, ranging from a simple
coordinating committee to a formal CCO that oversees all the different ICUs and/or step-down units within a medical center or network. Additionally even without a CCO, some hospitals have created a position called an associate chief of staff, associate chief medical officer, or an associate physician in chief who is responsible for all critical care operations. These programs are in line with the changes nurses have made for years putting all the ICUs under one umbrella. The evolution of critical care services or divisions to enterprise-wide CCOs has only rarely been studied [1]; potential benefits include system budgetary support for critical care, sharing of resources, protocols and best practices, group purchasing, plus physician and nursing cross-coverage in person or via telemedicine.
ICU ORGANIZATION: PHYSICIAN PRIVILEGES AND CARE MODELS

Although for the majority of countries worldwide the critically ill population is cared for in “closed” ICUs, the controversy around the “closed” versus “open” model of care continues to exist in the United States. In broad terms, there are three common models for ICU organization:

Open ICU: Traditionally, in an open ICU model unit, a primary physician with hospital privileges may admit and care for patients in any appropriate bed, including the ICU. Patient care decisions are made by the admitting physician, often with the input of consultants. Admission and discharge (triage) decisions fall to the ICU director only in the event of a bed or staffing shortage. Elective consultation with intensivists (when available) may be ordered at the discretion of the admitting physician. The major perceived benefit of this model is the continuity of care, although arguably less so when the admitting physician is a hospitalist rather than the patient’s primary care provider. By necessity, the open model remains prevalent in the United States, with greater than 50% of ICUs (typically in smaller hospitals) lacking daytime intensivist coverage [6].

Closed ICU: All patients are managed by a team of intensivists (physicians with specialty training in intensive care medicine) or in partnership with an admitting primary attending service for the duration of the ICU stay. Depending on local institutional tradition, the admitting physician may remain closely involved or collaborate from a distance. Theoretical benefits of this model include more timely patient assessment and treatment initiation; use of clinical protocols and checklists; and attention to evidence-based critical care with reductions in mortality, complications, resource use, and ICU and hospital length of stay (LOS). This model is most common in Europe, Latin America [7], Australia, and New Zealand but continues to gain acceptance in the United States, based on research findings and response to external pressure from the Leapfrog Group [8] and payers.

Intensivist staffing contributes to a hospital’s overall safety score, and smaller hospitals without full-time intensivists may find it difficult to achieve a Leapfrog Safety Score [8] of “A,” unless telemedicine is employed. Of interest, among the center participants in the Extended Prevalence of Infection in Intensive Care Study trial, 83% of them were a
Closed ICU units are frequently unworkable in smaller community hospitals where it would be financially prohibitive to support a full-time intensivist in a 4- to 6-bed ICU on net practice service revenue alone, especially with a poor payer mix. Although ample evidence suggests that on-site intensivists improve processes of care and staff satisfaction and decrease ICU complications and hospital LOS [10], other studies have found no difference in mortality with high-intensity daytime physician staffing [11]. There are little data documenting exactly what elements of the closed ICU organizational models are responsible for improvement of care.

**Transitional (Semi-closed or Hybrid) ICU:** Patients are referred for ICU admission to an intensivist, who reviews all admissions for appropriateness (gatekeeping). Final decisions regarding admission, discharge, and triage rest with the physician unit director or his/her designee. The intensivist may be responsible for some patients but not others and via specific consultation may participate in some or all of the patients’ care in conjunction with the patients attending physician. The intensivist’s role may be limited to triage functions and emergency response but more often encompasses hemodynamic, respiratory, fluid, nutritional, preventive care, and safety management. This model is seen in the transition phase between open and closed structures and remains common among surgical practices where the attending surgeon addresses overall supervision and the specific operative aspects of a patient’s care (e.g., wound care and transplant immunosuppressive regimens) while delegating emergency resuscitation, physiologic monitoring, organ system support, and ICU safety issues to the intensivist. Arguably, ICU telemedicine (discussed later) is becoming the dominant form of the semi-closed unit.

Pronovost et al. [12] conducted a systematic review of articles examining physician staffing patterns and clinical outcomes published through 2001. The model of care in each of 17 studies was classified as low-intensity staffing (a model other than closed or mandatory consult) or high-intensity staffing (closed ICU model or mandatory critical care consultation model). The high-intensity model was associated with lower ICU mortality (pooled mortality risk estimate = 0.61) and lower hospital mortality (pooled mortality risk estimate = 0.71). Although the literature overwhelmingly favors intensivist staffing models, a retrospective analysis of the Project IMPACT database by Levy et al. [11] demonstrated higher odds for hospital mortality for patients managed by critical care physicians. These counterintuitive findings have been challenged as being caused by differences between studies in ICU administration, team composition and function, and unmeasured confounders including case-
mix differences [9] and the role of trainees and part-time academic faculty [13]. The higher risk-adjusted mortality of teaching hospitals where more invasive interventions are performed [14] may also obscure beneficial effects of full-time intensivists.

Case–control studies, where outcomes have been examined before and after implementing a closed model, offer additional insight into the value of intensivists. Patients admitted to closed units tend to be sicker [15,16], as might be expected with tighter triage criteria. Nursing confidence in physician clinical judgment improves [17], because a closed system allows the nurse to contact one managing physician rather than having to call the pulmonologist for ventilator changes, the nephrologist for fluid and electrolyte issues, and the cardiologist for arrhythmias. These efficiencies are generally reflected in shorter ICU and hospital LOS [18]. The effect of dedicated intensivist staffing on ICU LOS remains significant after case-mix is adjusted for risk factors such as patient age, admission severity of illness, pre-ICU LOS, and percentage of patients requiring mechanical ventilation [19]. Moreover, the closed ICU model may decrease resource use by allowing the intensivist to reduce inappropriate admissions, lessen complications that may impact duration of stay, and enhance opportunities for more timely discharge from the ICU.
ICU PROVIDER STAFFING

Providing around-the-clock (24 hours × 7 days, or 24/7) intensivist coverage requires substantially more physician hours and thus costs more than the traditional model where intensivists may make daily or twice-daily rounds and are otherwise available if paged to return. Despite intuition that more intensivist hours in ICUs might provide better outcomes, there is no difference in risk-adjusted mortality or family satisfaction metrics with 24/7 staffing of ICUs in the presence of high-intensity daytime intensivists [20]. Additional data suggest that there are no differences, independent of severity of illness, in mortality, ICU and hospital LOS, or duration of mechanical ventilation when nighttime coverage of the ICU is provided by nonintensivists or trainees [17]. A single center trial found no differences of mortality or ICU LOS for a night shift intensivist compared to having an intensivist on call from home via phone contact [18]. Perhaps the nonsuperiority of a 24/7 model of care may simply indicate that protocolized ICU care set up and driven by intensivists during the day effectively reduces the need for intensivist presence at night. Although outcome differences can be demonstrated as a function of ICU admission time and day of week [21–25], at the hospital level, there is no statistically significant mortality difference based on the time of admission for most (77%) diagnoses [26], including acute myocardial infarction, congestive heart failure, pneumonia, stroke, gastrointestinal bleeding, and many surgical conditions. Mortality was higher, though, among patients with ruptured abdominal aortic aneurysms, acute epiglottitis, and pulmonary embolism, when these patients presented on a weekend rather than a weekday. Practically speaking, in-house 24/7 intensivist coverage is impractical for more than half of US hospitals, and efforts are now underway to properly educate the hospitalist workforce for this task [27].

A survey of CCOs from 23 academic medical centers (104 ICUs) revealed ICU models of care comprising full-time intensivists (33%), shift-work intensivists (28%), and a hybrid model of full-time and shift-work intensivists (26%). Physician extenders provided care in 36% of the ICUs with hospitalist involvement in 21% of medical centers. Fourteen percent of these academic centers provided ICU telemedicine services [1].
ICU TELEMEDICINE

In ICU telemedicine, critical care physicians, physician extenders, and nurses provide a team-based real-time support to multiple critical care units (CCUs) from a centralized location. Remote intensive care with ICU telemedicine has emerged as a partial solution to the shortage of intensivists. ICU telemedicine has grown from 0.9% of total US ICU beds in 2003 to 7.9% in 2010 [28]. Using intensivists and physician extenders to provide supplemental monitoring and management of ICU patients between noon and 7 AM, Breslow et al. were able to demonstrate reductions in hospital mortality (relative risk = 0.73), ICU LOS (3.63 vs. 4.35 days), and lower variable costs per case [29]. Given the critical shortage of intensivists, tele-ICU systems can potentially permit these specialists to monitor more patients including those who otherwise might not have access to an intensivist. Thus far, hospitals adopting ICU telemedicine have tended to be larger, urban, covered by residents, and located in large metropolitan areas [28], while a pressing need remains in small, rural hospitals without house staff.

There are numerous models of ICU telemedicine. These range from total 24/7 coverage by an intensivist at the control center with hospitalists or advanced practitioners on site to episodic night or weekend coverage with on-site intensivists conducting rounds and weekday coverage, or any variation of the above. Research is needed to determine how local hospital operating factors (i.e., level and experience of physician and nursing staffing, sophistication of the EMR and order sets, protocols, and local culture) affect the design of the telemedicine coverage [30].

Despite the shortage of data, the Leapfrog Group and the University Health System Consortium have encouraged the application of tele-ICU [31]. A major methodological limitation of “before and after” study design is the inability to control for other temporal changes in case-mix, staffing, and use of decision-support tools or new electronic medical software introduced at the same time. Potential benefits of ICU telemedicine include better adherence to evidence-based practice, continuous availability of critical care expertise, and better survival [32]. These must be balanced against costs, reimbursement, privacy and medicolegal issues, the potential for downtimes and malfunctions, and depersonalization of the patient–physician relationship inherent in introducing a layer of technology [31].

Additionally, there are many costs to implementing telemedicine that are in part determined by the sophistication of any existing EMR and ICU systems. Full telemedicine requires cameras and bidirectional
communication systems in each ICU room as well as the waiting room or conference room, interfaces for the ICU bedside devices as well as the EMR, and ongoing licensing fees. Installation can be turnkey, or built with “off the shelf” technology [33]. Thus, the capital costs of implementing and ongoing costs of maintaining telemedicine support can be substantial; more research is needed to determine whether cost-effectiveness is limited to certain circumstances or is more universal. Yoo et al. conducted a simulation analysis assuming per-patient per-hospital-stay ICU cost and hospital mortality based on published literature. Additional costs for tele-ICU were estimated at $909 to $1,057 per patient, and the mortality reduction from tele-ICU was to be 23.7% (range 18.5% to 28.9%). In this simulation, ICU telemedicine was cost-effective in most cases (considering a threshold of $100,000 per additional quality-adjusted life year), and cost-saving in some circumstances [34].
PHYSICIAN HUMAN RESOURCE ISSUES

Hiring full-time critical care specialists is already a challenge with the growing shortage of intensivists [35]. Critical care workforce needs have not been adequately addressed by public policy; the current reimbursement at Medicare/Medicaid rates is frequently insufficient to cover physician salary and benefits. Angus et al. predicted in 2000 that serious shortfalls would occur by 2020 [36], and these predictions still are on track, especially given differences between the number of Critical Care Medicine (CCM)-certified individuals and those actually practicing critical care [37]. Intensivists previously willing to work 66 hour/weeks and 10- to 12-hour shifts are finding nonbedside care alternatives as they age [38]. It is unclear that the next generation of intensivists will continue to work at this level of intensity or that critical care will even be a viable career choice when remuneration is better for specialties with shorter working hours and less stress. Typical schedules for emergency medicine physicians (three 12-hour shifts for 46 weeks or 1,656 annual clinical hours) or hospitalists (typically 1,760 hours per year) are already more attractive than standard critical care jobs, and it is likely that a reduced annual critical care workload will become a cost of doing business as older physicians retire.

Current Leapfrog Group standards call for *in-house* intensivist staffing for a minimum of 8 hours, 7 days per week [13,39], or > 2,920 hours per year to cover one ICU, with requirements for off-hours coverage met by an intensivist on beeper call, plus a Fundamentals of Critical Care Support–certified physician or physician extender immediately available in-house. Hospitalists have both potential value and limitations acknowledged in a joint position paper from the Society of Hospital Medicine and the Society of Critical Care Medicine (SCCM) [27].

It is helpful to consider the concept of a clinical full-time equivalent (FTE) to represent the amount of work done by one individual working only on direct patient care tasks in the ICU. In reality, some ICU clinicians will also allocate professional time to research, administration, or education; choose to work part-time; or spend part of their clinical time on the trauma team, in the pulmonary or sleep clinic, or in administering anesthesia. A full-time physician working only in the ICU might have grant funding for 0.25 FTE stipend and another 0.25 stipend for administrative and educational activities, leaving 0.5 FTE for ICU
clinical activity.

How many hours will one FTE work in a year? Respondents to an SCCM survey reported annual work hours from less than 1,000 to more than 4,000, but most commonly 2,000 to 2,500 hours [40]. Because attractive jobs currently offer at least 4 weeks’ vacation, about 10 paid holidays and at least 5 days of professional meeting time, for arguments sake, we will consider annual work to be 45 weeks with 10-hour days, yielding approximately 2,250 hours, within the range reported in the SCCM survey. If in-house coverage for the ICU is around-the-clock 365 days per year, with 30-minutes overlap for sign-out at the beginning and end of 12-hour shifts, then annual hours to be covered are 8,760; 8,760/2,250 implies 3.9 FTEs would be required to cover the workload, edging closer to 5.0 FTE if additional overlap hours are required or if annual clinical hours are reduced closer to hospitalist norms. Additional nonclinical time would be needed for administrative, educational, and quality assurance activities. In an academic medical center, clinical care time for full-timers is frequently set at 80% to 90% of paid hours (0.8 to 0.9 clinical FTE) to allow for teaching or administrative activities.

The ICU medical director will need significant administrative time (0.2 to 0.5 FTE, depending on the size of the ICU and the number of physicians and advanced practitioners supervised). If coverage is only during the daytime (3,650 hours per year), then fewer FTEs would be required; on-call hours must still be staffed, unless tele-ICU coverage provides full support [1]. In one survey of 152 ICUs at 24 academic hospitals, intensivists were in-house in 49%, with off-hours in house coverage provided by advanced practitioners (63%), hospitalists (21%), and via telemedicine (14%) [41].

Staffing calculations must consider intensivist-to-patient staffing ratios, which are not well defined. In England and Wales, where intensivists staff 80% of ICUs, the average 6-bed general ICU has three consultants committed to the unit and another three consultants participating in the on-call rotation [42]. A retrospective study from the Mayo Clinic [37] did not find differences in severity-adjusted mortality rates at daytime intensivist-to-bed ratios between 1:7.5 and 1:15 although ICU LOS increased at the higher extreme. Larger hospitals with closed units may take advantage of cross-coverage between units, providing daytime care at intensivist-to-patient ratios of 1:8 to 1:12 and increasing the ratio during off-hours when there are fewer acute interventions or procedures to be performed.

The number of critical care physicians is not increasing as fast as the number, size, and occupancy rates of ICUs, leading to a potential intensivist shortage [43]. A recent SCCM taskforce has made a number of recommendations for “closed” ICUs where intensivists control triage and patient care. Although they could not advocate a specific maximum
number of patients under one physician’s care, the taskforce concluded that proper staffing affects care, large caseloads should not preclude timely rounding, staffing levels should consider surge capacity, and regular institutional reassessment of staffing levels is necessary. In addition, high turnover rates or deteriorating quality indicators may be markers of overload, and telemedicine may be useful to alleviate overburden but needs more study. In teaching institutions, faculty and trainee feedback may illuminate the effects of understaffing on medical education, and there is some evidence that intensivist-to-patient ratios less favorable than 1:14 negatively impact patient care, education, and staff well-being [44].
MULTIDISCIPLINARY MODELS: ADVANCED PRACTITIONERS

Strategies suggested to offset the shortage of intensivists in the United States include the use of advanced practitioners to fill out 24/7 ICU coverage. Driving forces that have accelerated the employment of advanced practitioners include cutbacks of federal funding for residency training and Accreditation Council for Graduate Medical Education standards placing duty hour limitations at teaching hospitals for medical trainees [37]. Advanced practitioner is a broad term covering health care providers such as nurse practitioners (NPs), certified registered nurse anesthetists, certified nurse midwives, and physician assistants (PAs). An NP is a registered nurse who has completed substantial advanced training and will typically be independently licensed in the state where practicing. Following state licensure, NPs may seek national certification from professional nursing boards and/or pursue specialty certification. NPs have more latitude to practice independently, although scope of practice laws varies by state. PAs must complete an accredited education program, usually 2 years in duration, but typically requiring prior college and health care experience. PAs must pass a national examination to obtain a license and always work under a physician’s supervision. It is vital for the intensivist team to recognize that NPs and PAs directly out of school may have minimal CCM experience. Therefore, intense onboarding and ongoing education is required in order for expectations of critical care excellence from advanced practitioners to be satisfied.

NPs and PAs are increasingly involved in critical care. Surveys suggest that PAs provide care in approximately 25% and NPs in >50% of adult ICUs in academic medical centers in the United States [40]. A comparison of house staff–covered medical ICU care to that staffed by NPs and PAs functioning simultaneously in a single academic center showed no differences of mortality, readmission rates, or ICU LOS [45]. A prospective cohort study (2011 to 2013) comparing 90-day survival and ICU and hospital mortality and LOSs found comparable outcomes for critically ill patients cared for by advanced practitioner nurses and residents [46]. Nonphysician providers have been shown to improve patient satisfaction, LOS, mortality, and duration of mechanical ventilation [41]. NP and PA responsibilities may be focused on procedures or implementation of protocolized bundles of care [47], freeing the intensivists to deal with difficult diagnoses or the most complex management.
Introduction of NP/intensivist team–based care can be beneficial to patient outcomes, financial outcomes, LOS, and patient satisfaction [48]. An attending physician/NP team can safely manage former ICU patients admitted to a subacute unit, therefore allowing the intensivist/fellow team time to care for higher acuity ICU patients [44]. Decreased overall LOS and ICU LOS, lower rates of urinary tract infection and skin breakdown, and a shorter time to mobilization have been documented after the introduction of an NP team to neuroscience ICUs [49]. NP participation with weaning protocols for mechanical ventilation has been associated with greater reductions of mechanical ventilation days, ICU LOS, and hospital LOS when compared to pre-NP participation [50]. NPs and physicians in training had equivalent efficacies for performing the required tasks, but residents spend more time in nonunit activities (e.g., lectures and rounds) and NPs spend more time monitoring patients, talking to families, and collaborating with other health team members [44].

Sharing the Care

As health care financing transitions from fee-for-service (FFS) to global payments, it becomes economically viable to transfer tasks to other providers, so that each provider is working at the “top of their license” [51]. Figure 132.1 suggests an approach to sharing the care in the ICU environment. The universe of patient presentations can be plotted on the y-axis of “certain versus uncertain,” and the x-axis of “simple versus complex.” In an accountable care environment, critical care physicians can concentrate on efforts where confidence in the diagnosis is low, or physiology is unstable. Tactical comprehensive care (where the diagnosis is known) can be delegated to advanced practitioners. The lower left corner of the graph represents protocol-driven care that could be delivered by respiratory therapists and nurses (supervised by physicians), and advances in artificial intelligence may allow highly automated care. The goal is to redistribute the workload with limited intensivist resources to create capacity for additional uncertain or highly complex patients.
Economic and manpower concerns will require physicians to concentrate on situations where there is diagnostic uncertainty, high complexity, or both. When the diagnosis is certain and complexity is low, care can be protocolled and delegated to others. ARDS, acute respiratory distress syndrome; ARF, acute renal failure; CHF, congestive heart failure; DO, doctor of osteopathy; ECMO, extracorporeal membrane oxygenation; HFO, high frequency oscillation; LPVS, lung protective ventilatory strategy; MD, medical doctor; MSOF, multiple systems organ failure; NP, nurse practitioner; PA, physician assistant; RN, registered nurse; RRT, respiratory therapist.

A team-oriented culture characterized by timely communication is associated with a shorter ICU LOS, greater ability to accommodate the needs of patient families, and a higher quality of technical care [52]. Including PAs on house staff-directed ICU teams does not appear to affect the rates of occupancy, mortality, or complications for ICUs with well-established protocols for common ICU diagnoses [53].

Intensive care services are among the most urgent and costly aspects of health care in the United States, and national surveys indicate the need to accommodate between 50,000 and 68,000 patients per day [37,43]. Professional societies are projecting an inability to meet this demand with intensivists; therefore, the role of advanced practitioners, respiratory therapists, dieticians, pharmacists, and other professionals will become a major component of the health care delivery model for critically ill patients.
ROLE OF THE ICU DIRECTOR, DIVISION OR SECTION CHIEF, OR SERVICE LEADER

The Joint Commission requires that an individual be designated as the ICU director, but actual job descriptions vary [41]. At one end of the spectrum, the medical director may simply approve critical care policies and serve as a resource for questions that cannot be solved by nursing administration. He or she may triage only in times of high census and may have very little role in the bedside delivery of critical care, other than to his or her own patients. At the other extreme, the medical director may lead the team of intensivists and other professionals that assumes total responsibility for all patients occupying ICU beds. Associated tasks might include management of multiple units, patient flow management, fellowship training programs, development of advanced practitioner programs, billing, recruitment and retention of staff, QI, research, and representing and marketing critical care to the greater hospital community. These responsibilities may apply at a local traditional CCM service or division within a department or at the level of CCO. Typically, the local ICU director will have a close working relationship with the unit’s nursing manager/leader and interact extensively with other professionals (e.g., pharmacists, dieticians, social workers, clergy, and utilization management specialists). Essential character traits of the successful ICU director include willingness to collaborate, ability to delegate, trust in colleagues, and excellent communication skills.

Nonclinical duties for physician managers may consume more work effort than clinical responsibilities when committee membership, administrative tasks, budget preparation, educational activities, and the business of running the ICU physician practice are included. ICU occupancy rates and the number of patients misallocated to ICU beds decline with involved physician management [54]. Executive resolution of chronic process issues also impacts transitions of care (including ICU readmissions) by addressing policies to avoid postdischarge medical deterioration, improper triage, or administrative problems [55]. Knowledge of case management rules (and consultation with the physician advisor to hospital case management) can improve ICU performance relative to standards for levels of care.

Tasks performed by the ICU director can best be divided into strategic versus tactical (see Table 132.1). Strategic tasks involve the “big picture” including data analysis, recognition of patterns and trends, setting priorities, considering alternatives, and implementing change. The ICU director is often the champion for process improvement projects. Areas
deserving of strategic consideration include cost containment; the overall culture of the ICU; QI efforts; education of physicians, nurses, and other health professionals; optimizing the implementation of electronic medical systems; and coping with change driven by ICU, hospital, and external factors [56]. Developing a strategic vision, communicating it well, and leading by example are essential.

Tactical chores consist of the day-to-day, “hands-on” running of the unit. Leaving aside patient care, which in itself can fill the day, there are human resource issues, scheduling concerns, patient triage, bed allocation, and conflict resolution [57]. The ICU director may be granted by hospital policy the authority to intervene in any patient’s care and may also be charged with evaluating issues and complaints that originate from family members, nursing staff, other physicians, or hospital administration. Tools to assist with the tactical aspects of patient care include checklists [58] and electronic support systems. The danger is that tactical chores multiply to occupy all available time, leaving little time for strategic direction. Implementation of computerized order sets, therapist-directed protocols, and other “bundles” of care helps to minimize the individual, routine tactical decisions and leave more time for strategic thinking.

The difference between strategy and tactics reflects the difference between leading and managing. Applied to academic teaching rounds as an example, the attending physician or ICU fellow should be leading (strategizing), not getting lost in the details, but rather planning at a higher level exactly what broad changes and interventions will be required to get the patient recovered and discharged from the unit. In contrast, the residents or advanced practitioners should be patient managers (tacticians) who respond to the information flow of physical examination findings, laboratory tests, and radiology reports. They collect and analyze these data and develop a daily or even hourly plan. It is difficult to concentrate on both strategy and tactics at the same time, which argues for dividing the effort with a team approach. However, the strategic leader should not be isolated from patient contact, for it is the experienced interpretation of clues and subtleties that define the expert clinician [59].

The job responsibilities of the ICU director (and by delegation, the triage physician of the day) create an inherent conflict of interest. A treating physician’s fiduciary responsibility is to advocate for an individual patient’s best interest. As the ICU manager, however, there is a responsibility to do the most good for the greatest number of patients. The essence of triage is to maximize benefits for the group, even at the expense of an individual. In times of bed shortages, the ethical principle of beneficence (“do good”) may conflict with the ethical principle of social justice. The reader is referred to Chapter 34 for a more comprehensive
discussion of ethical issues in the ICU, but it is important for the ICU director to recognize these conflicts and preemptively construct ICU and hospital policy to address how such conflicts should be resolved.
BUDGET AND PROFESSIONAL REIMBURSEMENT ISSUES

The ICU director may be responsible for managing the budget of the entire CCU, including the nursing and respiratory therapy components, but more typically will be particularly concerned primarily with revenue from physician professional activity. In the United States, critical care revenue is generated by billing critical care codes (Current Procedural Terminology (CPT) codes 99291 and 99292) when the patient qualifies for time-based bedside critical care or otherwise for evaluation and management (E&M) codes (typically CPT code 99232-33 for subsequent hospital care and 99251-53 inpatient consultation) [60,61]. Various procedures have specific codes, and each code is associated with relative value units (RVUs) that form the basis for eventual payment. The connection between RVU generation and clinical effort in the ICU setting, however, is tenuous at best, in part due to the difficulty of documenting and billing the multitude of small tasks accomplished over the course of the day.

The majority of billable services may occur during the normal business day. Thirty-one to seventy-four minutes of bedside attention to one patient will justify a single CPT code 99291. Additional services rendered to that patient throughout a 24-hour period would have to exceed 74 total minutes to additionally bill CPT 99292. As a result, off-hours interventions may generate less income than what it costs to staff those hours, although revenue will depend on the number of patients seen, their severity of illness, and the reimbursement rate for a particular locale. In many institutions, revenue received may be 50% or less of what was actually billed, owing to low Medicaid rates and negotiated contractual agreements with insurers. Thus, under systems of reimbursement used in the United States, it may not be possible for a critical care physician group to be self-funding on patient care revenue alone especially when providing extended hours of in-house coverage. The landscape of billing and coding is constantly changing, and the 2015 Medicare Access and CHIP Reauthorization Act [62] encourages a transition from FFS billing to population health where global “per member per month” payments cover all medical care. Current information on CPT coding is available at the American Medical Association website [63] and through the SCCM [64].

The ICU director plays an increasingly important role for managing the business aspects of the critical care practice. It is helpful to have a tracking system to ensure that each physician is submitting his or her
patient care charges in a timely manner and that the billing service is properly submitting and capturing these charges. On a monthly basis, patient care volume, charges submitted, and RVUs should be reviewed for each provider and compared with budgeted amounts and past trends. Thus, individual physician performance by billing code should be tracked, not only for productivity, but also to ensure that codes are being used appropriately and consistent with a typical specialty profile. It would be unusual for all patients to qualify for critical care codes; some percentage of patients may only qualify for E&M billing, with or without additional procedures. Of note, for ICUs with advanced practitioners, the billing must account for the use of the CCM codes within a 24-hour period for all members of the CCM team that may include both attending physicians and the advanced practitioners.

Most US institutions perform periodic internal audits that help to confirm physician compliance with Medicare and insurer billing rules; it is easier and less costly to identify and rectify any issues internally. The alternative may be an external audit, where any errors detected in a small sample of charts will be applied proportionately over a multiyear period to demand a large retrospective repayment for billing errors. A provision in the American Recovery and Reinvestment Act of 2009 mandates annual fraud and abuse training for health care providers.

The Centers for Medicare and Medicaid Services (CMS) implemented a Recovery Audit Contractor program to review billing and identify over- and underpayment [65]. Regional auditing firms are paid on a contingency basis to review medical record documentation, especially the diagnostic specificity of admitting and discharge diagnoses, listings of comorbidities, and evidence of medical necessity as patients’ transition from care environments (e.g., operating room, recovery room, emergency department, inpatient vs. observation status). The coding of diagnosis-related groups (DRGs) comes under particular scrutiny, as does location of service (ICU, ward admission, or observation). DRGs likely to trigger review include many common ICU conditions including sepsis (vs. infection alone), acute respiratory failure (vs. acute systolic or diastolic heart failure), pneumonia, chest pain, and stroke (vs. transient ischemic attack). “Pay for performance” initiatives are increasingly tracking adherence to diagnosis-specific bundles of care; failure to document that elements of care have been completed can reduce hospital reimbursement.
MONITORING CLINICAL CARE

Good structure (attributes of the setting in which care occurs) facilitates good process (what is actually done), which hopefully promotes good outcomes (or results) [66]. Although the Joint Commission historically focused on structural elements such as medical staff organization, available equipment, and human resources, their emphasis has now shifted to analyses of process and outcome [67]. Most benchmarking currently takes place by outcome assessment, commonly using mortality and resource utilization as end points. Because patients present with different levels of disease and physiologic reserve, raw outcome measures such as mortality must be adjusted for severity of illness [68]. For the ICU, tools include the Acute Physiology and Chronic Health Evaluation (APACHE) system [69–71], the Mortality Probability Models (MPM) [72,73]; the Simplified Acute Physiology Score (SAPS) [74,75], and the Intensive Care National Audit and Research Centre (ICNARC) model [76]. These systems are based on large databases, report acceptable discrimination, and calibration and have been extensively examined in the peer-reviewed literature. However, only a minority of hospitals consistently collect this type of data. Although APACHE and MPM are generally used in North America, SAPS in Europe and South America, and ICNARC in Great Britain, models can be employed in any location as long as the model is recalibrated for the local environment [77].

ICU severity models facilitate comparisons between ICUs and are most useful for retrospective analysis of performance, with limited but improving utility for real-time management. Careful definition of data elements and outcomes to be collected enables comparison of local outcomes with national data.

An APACHE IV score is comprised of the Acute Physiology Score (“APS” see below), age, and chronic health items. The APS is generated by summing point values based on physiologic derangement in 17 variables and then adding points for age and chronic health status [78]. The APS is interpreted in light of the main patient diagnosis, patient location, and duration of hospital stay prior to admission to the ICU. Mechanical ventilation during the first ICU day and emergency surgical status also influence an individual’s predicted mortality. Although the error bars around the mortality estimate are large for any individual patient, the APACHE system has been shown to be quite reliable at assessing mortality outcome for sufficiently large groups of patients. APACHE IV is also useful for assessing ICU LOS (resource consumption) in groups of patients even though utility is limited for individuals [79].

The MPM-III model was developed and validated using Project
IMPACT data (an initiative of the SCCM) from 55,459 patients at 103 participating ICUs in North America [78]. With the acquisition of Project IMPACT by Cerner, the APACHE system and Project IMPACT have been consolidated into a single critical care information system that takes advantage of the ease and immediacy of the MPM score (generated on admission) with the more detailed, disease-specific predictions of the APACHE system at 24 hours and beyond. Plans call to extend the APACHE system beyond the ICU to a new product called APACHE Outcomes Across Venues [80].

Specialized scoring systems are more appropriate for pediatric [81], trauma [82,83], or cardiac surgical units [84]. Pediatric scoring (e.g., Pediatric Risk of Mortality) differs from adult scoring because of expected differences in normal physiologic ranges. Cardiac surgical systems downplay acute physiology, which is deliberately controlled by the operating room team, and emphasize variables such as left ventricular function, intra-aortic balloon pump use, and cardiopulmonary bypass time that might not be available or clinically relevant in other patient groups. Performance of the general severity models deteriorates when case-mix in an ICU becomes skewed [85]. APACHE-IV accommodates case-mix differences by including disease-specific coefficients. MPM-III provides subgroup models for use when an individual ICU’s case-mix is skewed from average [86], although the general model is essentially as good as specialized models for identifying performance outliers.

The primary clinical limitation of all outcome adjustment models is that they apply to the analysis of outcome in groups of patients, but not when making individual therapeutic decisions. At best, the prognostic estimates for an individual patient may be used in a probabilistic manner to predict bed or other resource utilization but could be inaccurate if applied as a prediction for application or denial of individual medical therapy, because of the uncertainty of individual estimates. A patient’s risk will change over time, making it problematic, for example, to use the admission severity score to determine eligibility for later therapy. In fact, ICU physicians discriminate between survivors and nonsurvivors more accurately than scoring systems, at least in the initial 24 hours of care [87].

ICU performance can be ascertained by generating predicted mortality rates for groups of patients using APACHE, ICNARC, MPM, or SAPS as a tool and then comparing observed actual results (numerator) to that prediction (denominator). The ratio of observed mortality to predicted mortality is called the standardized mortality ratio (SMR). An ICU with an SMR close to 1.0 would be exhibiting expected performance for its case-mix of patients. SMRs significantly greater than 1 indicate a higher than expected mortality, whereas SMRs less than 1 suggest outcomes better than expected. The sample size and distribution of patient acuities
will determine exactly how far from 1.0 (in either direction) the SMR becomes significant.

Events and therapy prior to ICU admission that alters physiology at admission create a “lead time” bias that has a measurable effect on outcome [88]. Because the SMR will be affected by differing use of postacute facilities and the percentage of patients with DNR orders, it may not always be valid in interhospital comparisons, unless applied to similar types of hospitals with similar policies [89].

Both clinical performance and cost-effectiveness should be considered when defining high-quality ICU care [90]. Rapoport and Teres initially described a method, since updated [91] that graphically displays both severity-adjusted clinical outcome and cost-effectiveness, using weighted hospital days as a proxy for cost. With this method, normalized severity-adjusted mortality is displayed on the x-axis and normalized weighted hospital days on the y-axis (Figure 132.2). Standard deviations of the normalized scale are displayed relative to the group mean at the origin (0,0). Units performing significantly better than predicted for both dimensions of care will chart in the right upper quadrant of the graph.

**FIGURE 132.2** Standardized clinical/resource utilization performance index (Rapoport-Teres plot). Hospital A has superior risk-adjusted mortality, while hospital B has a superior risk-adjusted length of stay. Hospital X has a short length of stay, but risk-adjusted mortality worse than predicted. Hospital Y has length-of-stay issues, while remaining within the expected severity-adjusted mortality range (risk-adjusted index of −1 to +1).
Individual hospitals may participate with proprietary organizations that assess quality at groups of member hospitals. In this setting, each hospital submits all of its clinical and cost data to the large hospital consortium which in turn crosswalks these data into a large universal hospital data set. Thus, the ICU data (i.e., admission rate, infection rate, occupancy rate, and mortality rate) of the individual participant hospital can be compared with other ICUs of similar hospitals and ICUs for benchmarking purposes [92].
Illness is commonly heralded by a constellation of quantifiable changes in physiologic and biochemical measurements. Abnormal values of selected physiologic measurements are useful as an objective indication of a patient’s risk level (as with severity scores) but may also be used “real time” to predict subsequent clinical deterioration on hospital wards. In theory, if hospital staff were to identify and provide interventions to these patients at an earlier stage, outcomes could improve, in terms of reduced intensive care admissions and LOS. Given that a number of studies have observed clinical signs of physiologic deterioration hours prior to a cardiorespiratory arrest, many hospitals have introduced a rapid response team (RRT) program and/or an EWS to facilitate the diagnosis and early treatment of patients with nascent clinical deterioration. The organization of RRTs varies among institutions with most hospitals offering some combination of a critical care nurse, respiratory therapist hospitalist, PA, resident, or fellow and smaller hospitals only having a single nurse.

Real-time surveillance of EMR data using EWS can be utilized to automatically activate an RRT team, but depending on sensitivity and specificity could potentially result in overutilization of the RRT without adequate benefits. At our organization, the EMR automatically flags patients with physiologic deterioration. Patient deterioration results in a notification on the nurse’s task list along with an e-mail message to the attending physician but does not automatically trigger the RRT response. Although the RRT could be summoned electronically, many systems have opted for nurse or physician notification to avoid overuse of the RRT.

Analysis postimplementation of an RRT model of care (also called medical emergency team) on hospital wards demonstrates 17% to 50% fewer cardiorespiratory arrests [93]. Few studies to date have shown any significant decline in the rate of unintended ICU admissions or overall hospital mortality with the introduction of an RRT model of care delivery. A 2010 meta-analysis by Chan et al. involving over 1.3 million patient admissions concluded that evidence supporting the effectiveness for RRT programs to reduce hospital mortality was lacking although there was a reduction in rates of cardiopulmonary arrest outside the ICU [94]. Clinical trial results have suffered from methodological limitations, varying staffing models, and limited number of randomized control trials. It is possible that the RRT involvement may boost end-of-life discussions and delivery of comfort care for patients on the wards that might
otherwise not have taken place, thus avoiding cardiopulmonary resuscitation and consequently not changing hospital mortality rates. Because EWS and RRT deployment will affect ICU resource utilization, ICU leaders need to be involved in planning, implementing, and maintaining these systems [95].
OPERATIONAL ISSUES

Nursing staffing levels are now subject to public scrutiny [96]. Excessive nursing workload has been shown to correlate with increased mortality [97], longer hospital LOS, increased complications [65,66], and the spread of resistant bacterial organisms in the ICU [98]. Adverse events have been reported to occur in about 20% of critically ill patients, with roughly half reportedly being preventable [99]. The most common cause of an adverse event is failure to carry out intended treatment correctly, often because of miscommunication or poor coordination of care [100]. Some hospitals have explored crew resource management training, adapted from the aviation industry, to improve team collaboration and coordination and ultimately improve patient safety. The medical director, in conjunction with the nurse manager and other professionals, will play a major role for defining and maintaining the organizational culture of the ICU. Disruptive physician behavior adversely affects nursing retention [101] and occasionally will require the intervention of the medical director, perhaps with the assistance of the hospital’s Physician Health or Medical Staff Health committee. Effective teamwork is essential, and team leadership is vital for promoting team interaction and coordination. Interdisciplinary communication is fostered by a number of formal and informal efforts. At a basic level, the format for daily interprofessional ICU rounds should encourage all members of the team to contribute information, ask questions, and make suggestions for the direction of care. Formal multidisciplinary rounds for long-stay patients, often held weekly, are useful when discussing the trajectory of care with the opportunity to collect additional insight from allied health professionals, social service, and clergy. Conferences, journal club, lectures, and research projects offer opportunities for beneficial interdisciplinary interaction.
QUALITY IMPROVEMENT INITIATIVES

ICU quality checklists are tools increasingly applied to ensure that basic issues (e.g., safety protocols, nutrition, and catheter removal) are not inadvertently forgotten during the inevitable “crisis mode” in a typical ICU day. Pronovost et al. showed that a combination of a checklist and a listing of daily goals reduced central line–associated blood stream infection rates [102].

As discussed earlier, ICU directors should be tracking severity-adjusted mortality, complications, and resource utilization (LOS). Increasingly, a balanced scorecard approach will also track patient satisfaction, typically via postdischarge surveys of patients through the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) program [103] administered by the CMS. Although ICUs are not specifically tracked by HCAHPS, the ICU stay is part of the patient’s hospital experience and can contribute to patient impressions. Items such as nurse responsiveness, physician explanations, and the ICU environment are considered in the questionnaire. Patient families deserve special consideration, especially because the family is likely to notice and appreciate the operational efficiencies and communication style that reflects the ICU’s culture. A multicenter evaluation of a scoring system for family satisfaction [104] identifies the key components for family satisfaction as assurance (the need to feel hope for a desired outcome), proximity (the need for personal contact and to be physically and emotionally near the patient), information (which should be consistent, realistic, and timely), personal comfort, and support (resources, support systems, and ventilation). Written materials (e.g., booklets and information sheets) can help meet family informational needs, especially with older, better educated patients and their relatives [105].
SUMMARY

Economic considerations continue to drive the agenda for hospitals and ICUs, and with the wave of “baby boomers” reaching retirement; increasing incidence of obesity, diabetes, and vascular disease in the population; and sporadic emergence of new threats, such as newer viral pathogens (e.g., Ebola, Zika, pandemic strains of the Influenza A virus), we can expect further changes. With a sicker, more chronic disease burdened population, hospitals have become places for the hyper-acutely ill, with much of recovery and recuperation outsourced to other facilities. Thus, intensive care will continue to consume an ever-greater proportion of total hospital costs, even as this growth becomes constrained by economics, bed shortages, and most importantly, insufficient numbers of nurses and physicians specializing in critical care. For many hospitals, what was once the province of the ICU has migrated to step-down and specialty units, leaving the ICU populated by the “sickest of the sick.” The advent of hospitalists and RRTs are but two manifestations of this continuing evolution in how care is delivered—the “ICU without walls.” These changes have forced a reevaluation of ICU organizational practices (increasing the value of “closed” units), human resource needs, a more management-oriented role for the ICU director, and critical care management approaches that involve shared decision-making by professionals from more than one ICU [106]. Benchmarking critical care outcome becomes essential for managing the increasingly complex world of the ICU, and we are on the threshold of having computerized real-time systems to automate some of the tactical decisions that occupy better applied professional time. Telemedicine, increased automation, use of physician extenders, and protocol supported care are all potential solutions to the impending crisis in critical care delivery. Continued change emphasizes the need for clinically and managerially competent physicians to organize and manage the increasingly complex world of critical care [107].

INTRODUCTION

In over 5 decades since the first implementation of the electronic health record (EHR) in the USA, there has been the rise, definition, and establishment of critical care medicine as a specialty and important force in health care both in research and practice.

Although technology has played an essential role for the creation of the specialty (e.g., ventilators and cardiovascular monitoring), the implementation of the EHR in US hospitals and intensive care units (ICUs) remained a meager 1.5% until the 2009 passage of the American Recovery and Reinvestment Act (ARRA), which included Health Information Technology for Economic and Clinical Health (HITECH) Act [1]. The HITECH Act stimulated the implementation of EHRs at US hospitals, owing to bonuses for achievement of “meaningful use” of information technology (IT), and penalties for failure of achievement. This represents the broadest single transformation ever undertaken of the clinical information infrastructure of US health care.

This chapter reviews a number of key components of IT in the modern ICU. The reader is introduced to some of the most important innovative technologies that have influenced the safe, effective, and efficient delivery of critical care services.

General information about the electronic medical record, departmental information systems, and coding and billing information systems is
extensively documented thus we assume that the reader has a working knowledge of these basic components of the modern health care information infrastructure. Herein, we address the ICU-specific IT functionality of greatest interest to the practicing critical care physician. In 2016, within the USA, core functionality for ICU record-keeping is primarily delivered through a core EMR system. The diagram below details a view of systems that sits adjacent to and above this core record keeping function that in many instances delivers ICU-specific functionalities, enhancing the value of the core record-keeping EMR system. In many cases these enhanced functions are delivered through the User Interface (UI) of the EMR and in some circumstances the workflow of the clinician or information content dictates that the knowledge be delivered through UI's that are adjacent or delivered in other formats such as mobile devices, or within the UI’s of bedside devices that monitor and deliver therapeutic care. In other parts of the developed and developing world, core record keeping functionality primarily resides within location-specific departmental systems that deliver workflow, decision support, and other functionalities listed in the diagram below either directly or in concert with supporting systems. Outside of the USA, the penetration of core EMR systems is currently limited but growing.

A schematic relationship between IT elements is outlined in Figure 133.1.

![Diagram of typical components of modern IT infrastructure in Critical Care.](image-url)

**FIGURE 133.1** Typical components of modern IT infrastructure in Critical Care.

In this chapter, we address (a) telemedicine in the ICU, (b) clinical decision support (CDS) systems, and (c) information systems for prediction of outcomes.

The most mature implementation of critical care clinical information
systems consists of tools which largely meet the needs of the hands-on caregivers. Historically, massive amounts of data documenting an ICU patient’s clinical status and treatment were recorded on large double-sided paper flow sheets, which were plagued with problems of legibility; inaccurate calculations; and use restricted to a single person at a time. By replacing this document with computer screens, each customized to a specific purpose, those problems have been improved dramatically.

Going beyond simple replacement of paper documents provides an opportunity to present information such that patterns are more easily recognized. For example, correlation of measures of physiological stability; clinical status (such as urinary output and body weight); and administration of medications can facilitate clinical analyses by juxtaposing interdependent variables. With these tools, physiological trends occurring over longer periods of time can be easily displayed, whereas in the past, these were laboriously drawn by hand.

Optimal use of clinical information systems should also guide the hands-on caregivers to provide care using evidence-based protocols. For example, simply creating a place to document the position of head of the bed underscores that this is an important issue to be managed in prevention of ventilator-associated pneumonia (VAP). Explanatory information can also be provided on a just-in-time basis to encourage protocol compliance. Computer provider order entry prompts and order sets can also facilitate standardization of care.

Collecting and displaying information electronically, in a coded, computable form makes these data available for continuous analysis, and enables detection of patterns of possible clinical deterioration. Collecting this information electronically also allows scrutiny of vastly larger datasets than can be retained and analyzed by the human brain. These analyses can also occur continuously and simultaneously for every patient providing a safety net early warning system that can notify clinicians of potential deterioration that may otherwise go unnoticed until significantly advanced.

Finally, computable information that describes in detail both the patient’s status and treatment can be used to analyze adherence to protocols for optimal care, resource utilization, and outcomes. Monitoring on a near real-time basis provides timely feedback and is an opportunity to intervene to improve ongoing care.

**Critical Care—Specific Technologies**

**The Electronic Flowsheet**

On the most basic level, Critical Care Information Systems (CCIS) put an end to juggling awkwardly large multi-page flow sheets. Like CPOE, they
eliminate the confusion and potential errors that can result from illegible handwriting and other issues that arise in a highly dynamic environment like the ICU. The truly significant contributions CCIS makes to patient safety are in the areas of care processes and medical decision-making. First among these is the ease of access to data. Access to a paper record can be problematic in the ICU, where multiple clinicians need to assess the patient’s clinical condition and response to treatment. Electronic records allow multiple caregivers to view the data at the same time, without waiting to access the one-and-only paper chart. Clinicians not in the ICU can also check on a patient’s status without physically having to be in the unit, allowing them to be consulted at the very moment their expertise is needed. When timeliness is critical, access is a critical enabler.

The impact of access on patient safety is enhanced when clinicians have confidence that the data provided are accurate and timely. By automating bedside data acquisition, CCIS ensures that relatively simple measures such as input/output and more complicated and time-consuming calculations such as hemodynamic calculations are presented. Once validated by a clinician, automated data becomes a part of the legal patient record. In addition, CCIS can automatically acquire data directly from monitoring equipment and ventilators, eliminating delays and errors of data gathering. Such automated data gathering provides today’s decision support systems with access to up to the minute data for surveillance and prediction. Today, the automated acquisition and utilization of real-time data is aided by advances of analytics and machine learning that allow systems to filter out outlier and erroneous data.

Unlike the paper flow sheet, with its fixed format, CCIS offer the potential for multiple displays of data. Each display may provide a problem-oriented view suitable for problem-oriented analyses. CCIS further supports the clinician by easing trend recognition. Specific displays can establish the correlation of events over time. Other displays provide multiday views, which are critical for measures like fluid balance and fever curves, surpassing the paper flow sheet’s view of only 1 day at a time. The displays in CCIS integrate multiple data elements that stood in isolation on the paper flow sheet. By combining vital signs, laboratory results, ventilator settings, medication drips, and medication administration, the CCIS enables clinicians to address the complicated clinical scenarios characteristic of critically ill patients in ICUs. This integrated record also assures attention to details that might be lost in a frenetic setting; for example, by issuing a warning that a medication is
overdue or being dosed earlier than appropriate per orders [2].

**Real-Time Clinical Decision Support**

CDS has been defined as a system that uses two or more items of patient data to generate case-specific advice [3]. In practical terms, CDS includes a wide range of functions, including predefined rules, alerts, reminders, workflow, and collaboration tools—and associated content—for improved medical decision-making [4–6].

Based on functionality CDS could be divided to six broad categories:

1. **Alerting**
2. **Interpretation**
3. **Assisting**
4. **Critiquing**
5. **Diagnosing**
6. **Managing**

CDS is often intended to facilitate the introduction of and conformance to evolving evidence-based medical protocols and standards of care while enabling appropriate individual physician discretion (such as during order entry). Basic CDS is frequently driven by rules which are built on IF/THEN logic statements. Rule-based CDS systems create recommendations that are often easily converted into human-readable form allowing clinicians to understand the logic underlying the CDS recommendations. Recent advances of machine learning and the availability of large-scale data with high-resolution physiological parameters have enabled the development of more advanced and complex CDS tools. Such complex CDS must also provide a means for clinicians to understand the underlying calculations and/or input parameters that lead to treatment recommendations.

Over the past decade, the primary user experience of CDS has been the alert message. A growing number of studies have revealed the critical limitation of alerts that, by design, interrupt the clinician’s workflow, in particular, during order entry [7,8]. The primary reason for this limitation lies in the fact that these CDS systems were designed mainly to alert post hoc—after the clinician has requested a particular item (e.g., drug, dose or test).

CDS has the potential to provide special value in settings like the ICU owing to the density of data routinely presented to the busy critical care physician and the ability of computers to combine, synthesize, and correlate these data and then create more complex rules and information
interpretation displays [6]. Studies have demonstrated that critical care rounds may challenge the physician with 20 times more data elements than the human brain can simultaneously process [7]. In the past, we have relied on the team approach to cope with this data overload. However, in the current practice reality of competing priorities for intensivist time and numerous handoffs among providers, there is a growing need for IT solutions to take more of a primary role in caring for the patient and unburdening the ICU clinician. Emerging developments in the areas of visual design and complex rules and algorithms aimed at addressing these needs for more automation to handle the massive amount of ICU data as described later in this chapter.

**Early Warning Systems**

In the ICU and throughout the hospital, specialized tools can address “failure to rescue,” which has been identified by the Agency for Healthcare Research and Quality (AHRQ) as accounting for the majority of patient-safety Medicare deaths. These tools provide proactive clinical surveillance, interpret patient data (which are collected by the CCIS), and act as early warning systems (EWS). EWS helps caregivers recognize critical data among the numerous data elements on every patient and may even provide early warnings for the Systemic Inflammatory Response Syndrome (SIRS), severe sepsis and other adverse conditions.

In failure to rescue, the patient experiences clinical decompensation over a period of hours, without intervention by caregivers. This error of omission occurs for any of several reasons. The changes of the patient’s condition may be subtle; for example, a physiological value may be decreased, but not alarmingly so unless viewed as part of a trend. In other cases, changes may not be appreciated for what they signify. Clinicians may lack the necessary expertise to discern such changes or may be overwhelmed with other tasks. Indeed, according to the AHRQ, there is strong evidence that level of staffing and the nursing skill-mix are both factors in this type of delay.

Delays for detecting changes are of grave concern for a simple reason: the earlier the intervention, the greater the likelihood for a better clinical outcome. Intervening at the first signs of decompensation may make it possible to avert cardiorespiratory and renal failure or address a more treatable complications. Studies of clinical instability suggest that patients experience symptoms before critical events like cardiac arrest. In one study, 70% showed evidence of respiratory deterioration within 8 hours of arrest; in another, 66% of patients showed abnormal signs and
symptoms within 6 hours [9].

Proactive clinical surveillance systems highlight trends and out-of-bounds values and conditions for further scrutiny. They provide displays—"dashboards"—that integrate different data elements to optimize evaluation of clinical problems. An additional feature offers severity scoring for the purpose of early detection of decompensation, issuing modified early warning scores to alert clinicians, especially on hospital wards, of developing but unrecognized problems.

Although early knowledge of patient deterioration is an important step for improving safety, a complete approach requires a mechanism to respond to patient deterioration as well. One approach is to create rapid response teams (RRT) or medical emergency teams [10,11]. The RRT consists of clinicians and nurses with critical care expertise that can be called anywhere in the hospital when a patient experiences acute physiological conditions.

**Concurrent Process Monitoring**

Concurrent process monitoring is also provided by CCIS and electronically monitors the details that define how adherence rates to a clinical care process. When data are captured and stored as discrete data elements, they are available for analysis. When analyses are concurrent (e.g., performed as care is delivered), this data allows managers and caregivers to have visibility into global processes of care. In the ICU, concurrent process monitoring allows evaluation of whether a particular practice is actually being implemented and whether it is affecting outcomes, such as elevation of the head of the bed to reduce the likelihood of VAP, or documenting the central line insertion bundle to decrease the likelihood of a Central Line Associated Blood Stream Infection (CLABSI).

Historically, organizations are good at creating policies and procedures, but much less effective in deploying them. Although it is easy to sit in a conference room and discuss policies and procedures it is much more difficult to get people to follow them. If data are extracted and tabulated manually, it is laborious to determine whether a particular practice is being implemented. Additionally, the reporting is retrospective long after the events being studied have occurred. In such cases, caregivers may believe “It used to be that bad, but now we’re better.” In contrast, concurrent process analyses allow the implementation of evidence-based practices by identifying and reinforcing practice patterns as they occur. Moreover, concurrent monitoring takes advantage of data already being gathered in the course of care, eliminating the need for duplicate data entry or chart abstraction.
Since the Institute of Medicine published its 1999 “exposé” on patient safety [12], the ICU has received increased national attention as an important target for medical error reduction and improved quality. Both the Leapfrog Group collaborative of large employers and the Centers for Medicare and Medicaid Services have focused on developing national performance measurement metrics for ICU and Acute Care [13,14]. Information Technology can be used to more easily gather patient, process, and outcomes data that support reporting solutions that facilitate improvement. Performance measures are typically categorized as structural (how care is organized), process (what is done), or outcomes (including medical/functional, such as death or the ability to perform specific functions of daily life); experiential, which covers both patients/families and providers; and financial, which includes both cost/resource use and profitability perspectives.

Structure and process measures are used on the presumption that their variance causes a specific significant variance in one or more outcomes. Popular examples of structural ICU measurable processes include intensivist coverage [14] and nurse staffing levels. Head-of-bed elevation for mechanically ventilated patients to prevent nosocomial pneumonia and associated increased mortality are examples of contemporary measurable processes.

One of the most significant challenges in quality improvement efforts is the lack of trust or alignment that can exist among clinicians, hospital administrators, insurance companies, and government over the motivation behind measurement. Clinicians believe that the purpose of measurement should be to understand and improve—although they too often, and too often rightly, assume payers’ and overseers’ plan to use metrics only to judge and to penalize—not to reward superior performance or improve patient care but only to drive down costs.

Given this environment, without standardized measures of meaningful medical outcomes that are defined, understood, and accepted by the relevant clinical community, making significant progress is difficult. Business intelligence systems, including performance dashboard techniques, that combine clinical data from computer-based patient records with financial data for analysis and reporting solutions are predicted to be an area of increased interest. As this evolution occurs, critical care leaders will want to assure that their unique information needs are met in these systems and that appropriate attention is given to
elements like risk adjustment and critical care-specific process analysis. Niche ICU analytical systems such as the Virtual Pediatric Intensive Care Unit (PICU) Performance System/National Association of Children’s Hospitals and Related Institutions, the Vermont-Oxford Network for neonatal intensive care, and Cerner Corporation’s Acute Physiology, Age, Chronic Health Evaluation (APACHE) prognostic, concurrent, and retrospective decision support system focused on adult ICU patients are also available [15].
RISK ADJUSTMENT MODELS FOR COMPARING ICU OUTCOMES

Risk adjustment, severity adjustment, or case-mix adjustment are terms used to describe mathematical models derived from large datasets of a particular population whose purpose is to represent the relative risks individual patients bring at the entry point to care process. Patient risk factors impact which care processes and resources are required to produce similar outcomes and what the best realistically achievable outcomes are. Modeling research needs to define three elements: (a) the binary or continuous outcome variable(s) to be modeled (e.g., lived/died, length of stay), (b) the beginning and end points in time (e.g., at admission to the ICU, at discharge from the hospital, at a specific time point like 100 days), and (c) the specific risk factors to be included (e.g., age/gestational age, weight/birth weight, diagnosis, physiology). Because many hospital patient records are still paper-based, the most viable data source developing risk adjustment has been those using administrative (claims) data, examples being APR-DRGs (all patient refined diagnosis-related groups) and disease staging. Model developers juggle the collection cost versus the desirability of capturing specific data, but unequivocally more detailed patient data than that included in claims databases are required to adequately represent patient-risk variance in the ICU population. Model developers also struggle with defining reasonable end points for capturing outcomes. They also need to consider and factor in relationships among institutions and settings, potentially “gaming” the system. A report card that inadequately adjusts for patient risk might under value hospitals and physicians who take on the highest risk patients, or encourage entities to transfer dying patients to reduce their mortality [15]. As Iezonni [16] notes, “developing risk adjusters de novo is complicated and often frustrating.” Risk models for adult, pediatric, and neonatal ICU populations have been sufficiently vetted and have sufficiently evolved to serve as the foundation for nationally standardized outcomes measurement in an increasingly automated hospital environment. Risk models need to be reevaluated periodically to assure that they remain consistent with current patient factors, care process improvements, and outcomes experience. They should also be evaluated for their appropriateness at geographies not included in their modeling datasets.

There are multiple risk-adjustment models in current use. Representative examples of ICU risk-adjustment models based primarily on US patient data include:
1. APACHE IV (Acute Physiology, Age, Chronic Health Evaluation, 4th version) [15,17]
2. PRISM (Pediatric Risk of Mortality) [18]
3. SNAP/SNAPPE (Score for Neonatal Acute Physiology) [19]
EVALUATING RISK-ADJUSTED OUTCOMES INFORMATION

Because risk-adjusted assessments are based on mathematical models, taking an objective approach to understanding the causes of variance data is logical. For example, there are four main causes of variance, and sequentially evaluating them helps clinicians gain familiarity with the models and acceptance of variance between actual and predicted results. These models include (a) data randomness (small sample), (b) existence of patient risk factors not incorporated or (c) adequately weighted in the particular model, and (d) variance likely attributable to differences in care.
EMERGING INFORMATICS TRENDS

Telemedicine

The realities of the critical care environment are such that patients may be critically ill and yet not be in a setting where their care needs can be expeditiously met. For example, a patient might be in a small or distant hospital where intensivist coverage is not available. Or, even in a tertiary or quaternary medical center, patients may decompensate outside the ICU and, indeed, even in the ICU after hours, an intensivist might not be physically present or able to respond.

Two technological approaches (on-demand consultative medicine and vigilance telemedicine remote monitoring) to dealing with this problem have been developed. Each is dependent on the availability of a suitably trained intensivist at a remote location equipped with a microphone and speaker and a high-bandwidth Internet connection, one or more high-resolution cameras (which may be controlled by the remote physician) and communication systems to speak with caregivers, patients and family who are in or near the patient’s room. Medical devices such as stethoscopes can be connected as well. Connectivity of the telemedicine system and the hospital varies according to institutional capabilities and can include access to the real-time physiological monitoring system; clinical information system; image archiving and communication systems; webcams, etc. [3]. Evaluations are still limited in that hands-on physician diagnostic and therapeutic maneuvers that can not be performed by available non physicians are not available when the physician is off-site.

On-Demand/Consultative Telemedicine

On-Demand or Consultative Telemedicine technology allows a remote caregiver to provide expert consultation from a location remote from the patient. This capability allows for distributed systems of care to effectively deal with relatively low frequency events such as effectively triaging suspected stroke patients to necessary levels of care or the treatment and safe transport of severely ill children who present for emergency care to institutions without the immediate availability of pediatric specialists and to guide pre-transfer resuscitation and stabilization.

A form of technology that is particularly well suited for the interaction with an individual patient is a mobile robot, offering what is referred to as “robotic telepresence.” One form of this device can actually be driven
remotely by the physician from its storage location to the patient’s location in the appropriately equipped facility. Using wireless connectivity, the robot establishes a similar connection to that which exists in rooms that have been specifically wired for these capabilities. As the costs of connectivity have decreased, institutions that formerly limited installations to those fixed in ICUs have been able to deploy telemedicine more widely across the hospital. It is clear that patients in other patient care locations can decompensate and may need to be monitored. Robots may provide a lower cost means to augment the expertise of rapid response teams.

Human-human interaction is a large part of successful implementation of Telemedicine systems. Interactions may be initiated by the caregiving staff from any care location. In such circumstances acceptance has been generally very favorable as nurses feel that trained physicians with access to patient data are available to help them and their patients at all hours.

**Vigilance Telemedicine/Remote Monitoring**

In institutions where multiple ICUs have been equipped with cameras in each room and connectivity to clinical information systems and other clinical data sources has been established, a team may be established at a central monitoring location which may be distant from the ICUs and hospital(s). Automated analyses and alerts of data from bedside monitors, mechanical ventilators and laboratory tests inform off-site providers to perform patient assessments. Alternatively, bedside providers can request evaluation and off-site management. Interventions, including the ordering of diagnostic tests, medications or consultations, or the manipulation of life support devices can be done by off-site providers or by their linked on-site providers. Thus, a single patient interaction may be initiated by the off-site physician as well as by hands-on caregivers. Like any team endeavor, effectiveness is determined in part by communication timeliness and dynamics of trust and responsibility among the bedside and off-site team members.

The primary responsibilities of the remote monitoring team are identification of unfavorable trends and to intervene to enhance best practice adherence, perform care plan reviews for patients admitted after day time hours and provide ICU pharmacist [20] and review of after hours medications orders which provides an additional safety net for patients in the ICU [20,21].

An important capability of remote monitoring is the opportunity to
perform virtual rounds on the sickest patients. The acuity status is used to identify which patients might most benefit from closer observation. In this way, the remote physician can perform virtual rounds at intervals customized to the patient condition to judge the effects of medications that may have been administered or support technologies and to determine whether physiological responses are improving or deteriorating. This surveillance can be an important complement to bedside care.

An additional role played by a central monitoring team is to identify when patients who are eligible for a protocol are not being managed according to an established protocol. It is important to recognize that clinical care protocols active at US hospitals require local hospital approval, which may include formal approval by an appropriate administrative body such as a physician Medical Executive Committee. For best alignment, protocolized care management by the remote monitoring team needs to conform to local hospital protocols.

Modern smartphones and small tablets have replaced many medical pagers and also provide the means to deliver high-resolution bedside monitoring device (BMDI) data, as well as complete access to the electronic medical record and highly automated decision support systems from any location at any time. Although telemedicine has enabled new health care structures, as noted earlier, these new technologies delivered to the individual practitioner are likely to transform medicine and the practice of telemedicine in the coming years in ways that are similar to their impact in the business world [22].

Predictive Analytics

Predictive analytics enable an organization to estimate or anticipate the risk of future events, and are used increasingly in other industries, such as for predicting consumer behavior. In health care, these techniques are often applied for planning demand for health care services and facilities; for identification of at-risk populations; and for actuarial projection of health care utilization or life span. Multiple Mathematical modeling and Machine Learning methods can be used for creation of models (Fig. 133.2).
CDS systems of the future will take more advantage of larger databases composed of increasingly granular patient data to drive pattern recognition engines that will help clinicians predict physiologic deterioration progressively earlier in the ICU course. Examples of predictive models in use today include the individual patient predictions components of the APACHE IV ICU models referenced previously [17], and the Northern New England Cardiovascular Disease Study Group’s preoperative mortality risk and cerebrovascular accident and risk of vascular complication models [23]. In addition, clinical registries for cardiac surgery, invasive cardiology, general surgery, and stroke, among others, can provide expected risk, complication and mortality models for a specific populations of patients. Not intended to replace but to support physician judgment, predictive models to date have focused on evaluating the appropriateness of ICU admission and readiness for discharge, assessing patient progress and effectiveness of current therapies, building care team consensus around prognosis and care strategies, identifying patients for palliative care assessments, and improving communications and setting realistic expectations with patients and families. Additional efforts now underway include a database being developed at the Mayo Clinic that incorporates clinical patient data along with genomic and expression data. The expectation is that powerful prediction models will result from analysis of this large-scale aggregated patient history, outcomes, and genomic dataset [24].

Another large-scale database is currently being collected and analyzed by a collaborative of industrial, medical, and academic partners (MIT,
To date analysis of this dataset (MIMIC II) has resulted in several prediction models that provide “early warning systems” for several specific types of physiological deterioration. One such model consists of a rule set that, when applied to near real-time patient physiological data, is capable of predicting hemodynamic deterioration hours before its occurrence [26,27]. Early warning alerts from advanced CDS systems hold the promise of improving response times to patient events. Although it seems to logically follow that such early identification of physiological deterioration would allow earlier intervention and prevention of patient crises, the effects of these interventions on patient outcomes are yet to be determined. Another example of a multidimensional near–real-time database is the ICU datamart of the Mayo Clinic. This data system includes laboratory, radiology, medication, fluids, physicians’ notes, nurses’ flow sheet data as well as CPOE. It contains over 250,000 ICU visits over 13 years [28].
ADVANCES OF DATA VISUALIZATION

Although many organizations have successfully applied performance metrics, severity scores, and predictive risk models for improved quality and decision-making, data collection/calculation and integrated display is likely to expand more in the next decade than in all previous ones. Designers have much work to do to accomplish meaningful display of the most important patient, process, alerting, and predictive information without overloading the clinician’s ability to absorb and respond. Three examples of the application of modern data visualization techniques are represented in Figures 133.3 to 133.5.

**Figure 133.3** ICU metrics dashboard. A comprehensive ICU performance management dashboard, as used by the Memorial Hermann Healthcare System in Houston, Texas. Note the integration of different categories of metrics, such as census; occupancy; glycemic control; infection prevention bundle compliance; medication and ventilator utilization; financial data; and patient outcomes. This is a fully automated monthly report that is electronically distributed to ICU and executive management across the health system.

Hospital-acquired infection indicators dashboard. A comprehensive real-time ICU hospital-acquired infection (HAI) dashboard, including HAI rates and detailed bundle compliance results for prevention of catheter-related bloodstream infection and VAP. This is a live intranet web display that is updated constantly. Both reports are widely available within the Memorial Hermann system and have helped drive performance excellence. Near real-time availability of bundle compliance and hand hygiene data have driven the incidence of CLABSI and VAP to zero or near zero levels across the Memorial Hermann system [29].

Courtesy of Memorial Hermann Healthcare System, Houston, Texas.
In conclusion, the modern CCIS is a dynamic information instrument or set of functionalities delivered by a core EMR that extends the capabilities of the intensive care physician and staff in ways that would be considered science fiction only a generation ago. The rapid adoption of these new information tools is now anticipated, as the complexity of medical care, particularly in the ICU setting, becomes increasingly demanding and evidence-based decision-making moves from a goal to an expectation of acute medical care. The most critical element, to taking advantage of these new possibilities, is that senior medical executives, ICU directors, and clinicians must “own” responsibility for localizing and embracing performance metrics and the advancing base of evidence-based decision support being made available by these new tools.
ACKNOWLEDGMENTS

The authors would like to thank the previous authors of this chapter who provided an excellent basis for this edition. We are very grateful to William F. Bria, MD, Richard M. Kremsdorf, MD, and Violet L. Shaffer for their foundational work on this topic—much of which remains within this chapter.
REFERENCES

Patient safety has become a major concern of the general public, policy makers, and local, state, and national governments. Frequent news coverage has been devoted to victims of serious medical errors. In the 1999 publication of the Institute of Medicine (IOM), “To Err Is Human: Building a Safer Health Care System” [1], the substantial risks of American medical care were highlighted, particularly the nearly 100,000 deaths per year that could be attributed to medical errors.

The importance of a safety culture in the high-risk environment of the intensive care unit (ICU) is becoming increasingly recognized and promoted [2]. In order to be effective, the development of a culture of safety must represent a central structure that promotes patient well-being through the use of coordinated intra- and interdisciplinary networks. Such a culture emerges from the presence of leaders who are committed to safety. Of equal importance is staff who understand that errors are inevitable, acknowledge that errors are to be reported, dedicate time to learn about new risks and hazards, support teamwork and open communication, and upgrade procedures and implement safeguards on a continuing basis [3]. Organizational characteristics of safe programs with low accident rates include successful safety programs with strong management commitment, safety training as part of new employee’s training, frequent open contacts between workers and management, general environmental control and good housekeeping, a stable
workforce, and positive reinforcement for good safety practices. Similar to other areas of the hospital environment, the ICU benefits from integrated systems that identify patient safety problems and report them to providers so they can improve performance.

On a broad scale, ICU patient safety reporting systems identify trends and patterns, allowing healthcare organizations, governmental agencies, and private accreditation organizations to monitor the quality and safety of healthcare delivery [4]. Patient safety reporting systems also have the potential to create large data repositories that inform the development of strategies to reduce the risk of preventable medical incidents [5,6]. In the 2003 report, “Patient Safety: Achieving a New Standard of Care,” the IOM emphasized the importance of standardizing information on patient safety to improve outcomes of care [5], including the development of a common taxonomy of patient safety terms. Standardized terminology permits healthcare providers to capture and describe events in consolidated reports [1,7,8]. To date, governmental and private sector accrediting bodies have not coordinated their efforts to develop actionable, integrated, validated, and reliable systems to measure and report medical errors and patient safety [9]. A recent trend involves more direct regulation by government agencies like Centers for Medicare and Medicaid Services (CMS) and state health departments. In some cases, mandated reporting and specific treatment algorithms have been recommended for critical illness like sepsis and ventilator-associated pneumonia. This chapter will explore the elements of patient safety in the ICU, related definitions, culture, education, and trends in the regulatory environment.

SAFETY LESSONS FROM OTHER INDUSTRIES

Safety and error prevention in the healthcare setting compares unfavorably with that of aviation, banking, chemical manufacturing, and peacetime military services. Approaches to safety used by these industries include well-defined strategies to protect workers and customers. Technology-based approaches are part of this strategy, but organizational and psychological factors contribute as well. For example, developing a culture of safety has been identified as one important method of improving safety. The aviation industry has focused on the importance of teamwork in reinforcing a safety culture.

Although technical, organizational, and psychological interventions have been effective for other industries, it is also worth noting the limits of these methods. Persistence of fatalities for the aviation and auto
transportation industries suggests that safety efforts may be counterbalanced by other competing risk factors such as high volumes, greater complexity of the product, cost pressure, and rapidly changing designs. These risk factors are particularly relevant to healthcare because the patient population is changing (with greater numbers of very old, immunocompromised, and high-risk patients), and technology is evolving at very rapid rates [10]. Thus, there is likely an upper limit in terms of cost-effective healthcare safety that can be reached. However, this level has yet to be attained, or even identified. Health services are being encouraged by the IOM report to aim for an error rate of less than 3.4 per million, that is, “six-sigma quality.” The discipline of anesthesiology in particular has made substantial contributions through its development of a safety culture and equipment manufacturing standardization, resulting in a reduction in anesthesia-related deaths to 4.4 per million, that is, “five-sigma standard.”

To achieve the six sigma level for ICU patients, there must be precise definitions of the terms needed to study patient safety, their methods of measurement, and the applications of these methods to the special problems of ICU organization within government regulations. Specialized physician training and development of a culture of safety will also be essential in order to achieve such an excellent level of safety in the setting of intensive care.
DEFINITIONS

The basic terms in common use to define concepts of patient safety are listed in Table 134.1, along with the working definitions of these terms that have entered into the lexicon of the patient safety industry [11]. Healthcare quality is defined by the IOM as “the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge” [3,12]. The IOM has also listed several attributes of quality care that define quality care as being safe, patient-centered, timely, effective, efficient, and equitable [13]. Thus, patient safety is one domain within the broader concept of quality.

### TABLE 134.1 General Terms Used in Patient Safety

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Quality</td>
<td>The degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge</td>
</tr>
<tr>
<td>Patient safety</td>
<td>The absence of the potential for, or the occurrence of, healthcare-associated injury to patients created by avoiding medical errors as well as taking action to prevent errors from causing injury. Freedom from accidental or preventable injuries produced by medical care</td>
</tr>
<tr>
<td>Medical errors</td>
<td>Mistakes made in the process of care that result in or have the potential to result in harm to patients. Mistakes include the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim. These can be the result of an action that is taken (error of commission) or an action that is not taken (error of omission)</td>
</tr>
<tr>
<td>Active errors</td>
<td>Errors that occur at the interface between a human provider and a care delivery system (e.g., mechanical ventilator, intravenous pump) and typically involve readily apparent actions (e.g., adjusting a dial incorrectly)</td>
</tr>
<tr>
<td>Latent errors</td>
<td>Less obvious failures of a healthcare organization or structure that contributed to errors or allowed the errors to harm patients. An example of a latent error would be understaffing of nurses in an intensive care unit</td>
</tr>
<tr>
<td>Serious medical errors</td>
<td>A medical error that causes harm (or injury) or has the potential to cause harm. Includes preventable adverse events, intercepted serious errors, and nonintercepted serious errors. Does not include trivial errors with little or no potential for harm or nonpreventable adverse events</td>
</tr>
</tbody>
</table>
Intercepted serious error: A serious medical error that is caught before reaching the patient
Nonintercepted serious error: A serious medical error that is not caught and therefore reaches the patient but because of good fortune or because the patient had sufficient reserves to buffer the error, it did not cause clinically detectable harm
Nonpreventable adverse event: Unavoidable injury due to appropriate medical care
Preventable adverse event: Injury due to a nonintercepted serious error in medical care
Slips: Failures of automatic behaviors or lapses in concentration (e.g., forgetting to perform a routine task due to a lapse in memory) and often occur from fatigue or distractions in the workplace
Mistakes: Incorrect choices, such as choosing the wrong drug, a clinical condition and typically result from inexperience or lack of knowledge or training
Incident: An event or circumstance that could have, or did lead to, unintended and/or unnecessary harm to a person
Harm: Death, injury, suffering, dissatisfaction, or disability experienced by a person
Near miss: Any incident that could potentially lead to patient harm
Adverse event: Any injury due to medical management, rather than the underlying disease

Patient safety has been defined by the Agency for Health Care Research and Quality (AHRQ) as “the absence of the potential for, or the occurrence of, healthcare associated injury to patients created by avoiding medical errors as well as taking action to prevent errors from causing injury” [14] and “freedom from accidental or preventable injuries produced by medical care” [15].

Within this context of safety, medical errors are defined as “mistakes made in the process of care that result in or have the potential to result in harm to patients. Mistakes include the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim. These can be the result of an action that is taken (error of commission) or an action that is not taken (error of omission)” [14]. Errors of commission (e.g., ordering an incorrect drug dose) are more readily noted than errors of omission (e.g., failure to order heparin for venous thromboembolism prophylaxis). Errors are further classified as active or latent [16,17]. Active errors occur at the interface between a human provider and a care delivery system (e.g., mechanical ventilator, intravenous pump), and typically involve readily apparent actions (e.g., adjusting a dial incorrectly). Latent errors define a less obvious failure of a healthcare
organization or structure that have contributed to errors or allowed the errors to harm patients. An example of a latent error is understaffing of nurses in an ICU. Other typologies include domains that ascribe characteristics of preventability, seriousness, and whether the error was intercepted before affecting a patient [18] (Table 134.1). The concept of medical error has become increasingly elastic because government regulation has further encroached on medical decision-making, as in the case of “ICU bundles.”

Errors have also been classified as slips or mistakes. Slips are failures of automatic behaviors or lapses in concentration (e.g., forgetting to perform a routine task due to a lapse in memory), and often occur from fatigue or distractions in the workplace. Mistakes represent incorrect choices, such as choosing the wrong drug for a clinical condition, and typically result from inexperience or lack of knowledge or training. The remedies for these two types of errors differ; slips are more responsive to removing distractions from the workplace or automating monotonous tasks, whereas mistakes respond to increased training or supervision.

Incidents are defined as unexpected or unanticipated events or circumstances not consistent with the routine care of a particular patient, which could have or did lead to an unintended or unnecessary harm to a person, or to a complaint, loss, or damage. Adverse events are different than incidents and are defined as an “untoward and usually unanticipated outcome that occurs in association with health care” [14] or in the broader terms of the IOM as “an injury resulting from a medical intervention” [1]. The Critical Care Safety Study defines adverse events as “Any injury due to medical management, rather than the underlying disease” [18]. An adverse event does not necessarily mean that the event was related to poor quality care [19]. As an example, if proper procedures are followed for central line placement but the patient develops a pneumothorax, this would constitute an adverse event. Errors of diagnosis have been less studied but are emerging as equally important causes of unsafe patient management in the ICU [20]. As the safety and quality movement has progressed, it is increasingly difficult to look at one aspect isolated from the other. Although it may be useful for research purposes to identify issues as either safety related or quality related, on a day-to-day basis the distinction between safety and quality issues is increasingly nominal.
MEASUREMENT OF SAFETY IN THE INTENSIVE CARE UNIT

Patient safety analysis can be viewed from the perspective of whether the measure identifies a structure, process, or outcome related to safety. Structure is defined by the physical environment and plant (buildings, equipment, information technology resources). Process and outcome can sometimes be conflated but in fact are distinct. Process refers to the way healthcare is delivered, i.e., how the system of care works. Outcomes are the downstream measures of health status. The most concrete outcome is mortality; the term can also include quality of life measures, specific morbidities, exercise capacity, and others. An additional dimension worth considering is the context in which care is delivered, also called “safety culture.” This reflects the attitudes and beliefs of local healthcare providers as well as the medical community at large. Measurement of this dimension, while difficult, may be worthwhile as there is some evidence that variations in culture are linked to clinical outcomes [21]. The primary methods of measuring safety culture include incident reporting, targeted monitoring, use of discharge data sets, process of care measurement, trigger tools, ICU audits, and direct observation [18].

Incident Reporting

In terms of collecting safety measurement data, traditional methods based on incident reporting of specific adverse events have been largely ineffective for several reasons [22]. First, reports have been generated in a punitive environment that focuses on the provider who committed an error rather than on systems of care, and thus discourages self-reporting of errors [5]. Second, each report of an error represents a “numerator” value that does not give insight into the denominator pool of patients at risk of similar errors. In the absence of these values, the incidence of errors and the overall safety of an ICU cannot be assessed. Third, definitions of errors used by incident reporting systems vary, which impedes data synthesis, analysis, collaborative work, and evaluation of the impact of changes in healthcare delivery [23]. And fourth, appropriate functional data spanning the domains of structure, process, and outcome are not collected, which impedes the ability to “deconstruct” an error to understand its root causes and patient impact.
Recent advances in incident reporting have enhanced the detection and analysis of errors. Internet-based systems allow anonymous reporting of errors, encouraging providers who have either committed an error or have knowledge of an error to enter related information into a central data repository [24]. The Intensive Care Unit Safety Reporting System (ICUSRS) is an anonymous reporting system that focuses on “systems factors” rather than “person factors” and provides expert analysis with feedback and guidance to improve processes of care and prevent error recurrences [11,25]. The University Health Systems Consortium’s Safety Net reporting system can generate consolidated reports with application to the ICU [24].

Institutional commitment to a “culture of safety” has a motivational effect on error reporting because healthcare providers recognize that “someone is listening.” The mere fact that errors are reported and there is accountability can generate improved quality of care if the system works properly. This culture requires several essential process elements to enhance error reporting: A team (a) convenes to develop preventative solutions to a reported error, (b) generates plans to improve the care, and (c) has a method for implementing and measuring the impact of their plan [23]. However, problems remain with the taxonomy used to describe errors and adverse events. The Joint Commission (JC) published a patient safety event taxonomy and classification scheme for near misses, errors, and adverse events [11]. The taxonomy used was designed to conform to an analytical framework and common word usages to promote its use and the understanding of its output. Data entered allows classification of a patient safety event within five complementary primary groups: impact—the outcome or effects of medical error and systems failure, commonly referred to as harm to the patient; type—the implied or visible processes that were faulty or failed; domain—the characteristics of the setting in which an incident occurred and the type of individuals involved; cause—the factors and agents that led to an incident; and prevention and mitigation—the measures taken or proposed to reduce incidence and effects of adverse occurrences.

The ICUSRS reporting platform uses a similar framework for evaluating factors that contribute to an incident [11]. Both the JC and ICUSRS systems recognize that errors are multifactorial and therefore include multiple variables along the three domains of structure, process, and outcomes, such as caregiver performance, systems of care, resource availability, functioning of teams, and the environment of care. These systems describe events with a multidimensional taxonomy to facilitate the comprehensive description and full deconstruction of errors to determine their root causes [9]. However, even if the taxonomy issues of incidence reporting are improved, the problem of determining the true incidence rate remains. A comprehensively described and deconstructed
incident only gives insight into the numerator; it does not provide information on the number of patients at risk and does not allow determination of true incidence rates.

**Targeted Monitoring**

A complementary approach to incident reporting is targeted monitoring. ICUs can measure their patient safety outcomes by monitoring a specific indicator, such as the incidence of *Clostridium difficile* infection in the ICU or ventilator-associated pneumonia. In so doing, ICUs are challenged to define their denominators and select indicators that can be readily detected and counted to provide an accurate numerator. The denominators are especially difficult to determine because these measurements have major impacts on interpretation [11]; for instance, *C. difficile* infection rates can be described per ICU patient, patient ICU days, or at-risk patient ICU days. The numerator data are equally challenging because of the time and expense of chart extraction needed for their collection. If the characteristics of the patient population change over time, then these factors must be accounted for as well. For example, if the patient population changes or new services such as transplantation are offered by a given hospital, then the patient mix will change and adjusted hazard rates will be needed. Thus, for this approach to be effective, a multidisciplinary team that includes people with ICU training, organizational skills, database management, and epidemiology is needed.

**Discharge Data**

Discharge data represents a potential source of information to allow the retrospective collection of quality and safety indicators to profile ICU performance [26–28]. Recently, AHRQ has developed empiric measures of quality and safety from multistate discharge data in a redesign of the original Healthcare Cost and Utilization Project Quality Indicators [29]. The Patient Safety Indicators are relevant to ICU safety of care. Although most of these indicators relate to surgical patients, newer indicators are being designed to measure the safety of care for medical patients with critical illnesses, such as myocardial infarction, stroke, and congestive heart failure.

Although this method is powerful and can be quite useful, it is important to also recognize its limitations. Discharge data analysis gives insight into outcomes, but little information on structure or process. Large data sets such as these also have limited data quality for clinically relevant covariates, so controlling for confounders is difficult. Because all of the clinically relevant covariates are not included, the problem of residual confounding is always a problem and caution should be exercised when interpreting results. Making interinstitutional
comparisons is therefore difficult, and even when trending data over time, results must be analyzed with caution. When patient populations and their problems are relatively homogenous and stable over time (e.g., surgical patients), this is a good system. When there is marked heterogeneity in terms of clinical problems and rapid changes in process of care over time, this approach will face difficulties. Having said this, discharge data sets can be an important tool for hypothesis generation so that ICU leaders can then launch more systematic studies of particular problems.

**Process of Care Measurement**

Safety can also be measured through determination of the proportion of patients who receive certain processes of care that have a strong evidentiary base for improving clinical outcomes. However, it may be difficult to isolate and ascertain the contributory effect of influential factors, such as adherence to best practice by the caregiving team, the role of complications, or level of care. Physicians and other clinicians often have a stronger sense of accountability toward a process measure than an outcome measure because the process measure can be more strongly linked to a particular care provider or team behaviors [30]. Physicians may also believe that outcomes can be overly influenced by severity of disease and prove resistant to quality improvement efforts. To serve as an accurate measure of safety and to influence quality improvement, process measures must have a causal relationship with the outcome they intend to represent.

Examples of process measures include approaches to ordering therapy in the ICU. Medication errors and adverse drug events occur commonly in the ICU [31] and can be limited by the use of formatted or electronic drug-ordering forms [32]. Computerized physician order entry (order-sets) for drugs has the potential to decrease the rate of serious medication errors [33] and to improve clinical outcomes when applied to antibiotic prescribing [34]. Additional care processes that should be in place to support patient safety can be constructed by adding allergy or drug–drug interaction monitoring and reviewing evidence-based clinical practice guidelines [35], such as standardizing orders for ventilator management in the ICU [36].

Process of care measurement is often very effective for certain types of problems (like computerized order entry), but it is important to recognize some of the limitations and difficulties inherent in this system when applied to more complex problems. When strong evidence-based clinical
practice guidelines are available, it is a feasible strategy, but often this is not the case. In addition, properly identifying those patients eligible for a particular protocol during the appropriate time period is critical. Examples include the use of thrombolytics for myocardial infarction and stroke. Determining the numerator for such process of care measures is fairly easy (who actually received the drug), but determining the denominator can be more difficult and can be costly because of the time and expense needed for data collection (e.g., reviewing every chart in the emergency department of patients presenting with angina or suspected myocardial infarction). In addition, chart abstraction in such cases usually requires a high level of expert judgment, which makes it variable, difficult, and costly. Thus, process of care measurement, because of cost and time considerations, may be a suitable approach to improving safety for those problems in which there is a strong evidence base and for which the costs of identifying the patient population (both numerator and denominator) are sustainable and warranted by the value of information obtained.

**Intensive Care Unit Audits**

An audit of the existing structure of an ICU can also measure patient safety. Evidence supports improved outcomes in ICUs staffed by sufficient numbers of board-certified intensivists [37,38]. Additional structure measures of safety include the presence of resources to establish ongoing competency of medical staff and residents [39], adequate nurse staffing and skill sets [40,41], and appropriate technology resources, such as smart pumps and bar coding [42]. Surveys exist that allow ICU directors to assess the status of their units’ culture of safety [43–46]. Pronovost and Sexton [45] recommend measuring the entire hospital annually with the full Safety Attitudes Questionnaire that has construct validity and sufficient reliability for measuring the single construct of safety culture. Once measured, the culture of safety can be improved with focused interventions geared toward any low-scoring hospital areas, such as an ICU.

**Trigger Tools**

Trigger tools refer to techniques used to detect organizational signals for adverse events. For instance, orders for flumazenil may identify patients who were given an overdose of a benzodiazepine drug. The flumazenil order, therefore, would serve as a trigger to perform a chart review. A trigger or set of triggers can be used to identify medical records for retrospective review to assess organizational safety, or used in “real time” as a tool to identify a specific patient at risk of an adverse outcome. Trigger tools for the ICU have been shown to be a practical approach to
enhancing detection of adverse events among critically ill patients [47].

Limitations of Existing Metrics and Their Applications

Currently, the majority of data collected to measure safety is process oriented. However, there is only limited evidence that the use of current process measures translates into better outcomes [48,49]. Quality metrics that include patient outcomes would provide better information to inform benchmarking and to assist in policy development, but proper assessment of ICU outcomes often requires extensive abstraction of clinical data, which can be prohibitively costly. In addition, risk adjustment to facilitate valid comparisons increases the amount and complexity of data abstraction required, further increasing costs. Sometimes the benefits of such safety programs warrant their costs. This is especially true when events are rare, which is usually the case with safety. In such instances, proper measures require collecting information on a very large population, which constitutes the denominator of the rates being measured.

It is also very important to consider carefully the attributes of performance measures and how the measures are arrived at. To be valid, measures usually have to be rates, defined as an event per person time at risk. This is different than a proportion, which has events per case, with no measure of time at risk. Most “rates” reported in the patient safety literature are actually proportions. For some outcomes, such as pneumothorax following lung biopsy, a proportion may be suitable. But for many other outcomes, person time at risk is relevant (e.g., ventilator-associated pneumonia), and a proportion will not suffice. In addition, the magnitude and direction of bias for reporting can be greater than the true variation of outcomes. This is because most reporting systems, such as the Patient Safety Reporting System, provide data from a non-randomly selected sample and the population at risk is not known. When interpreting safety metrics, careful attention must be paid, bias must be considered, and all results should be viewed with caution.

An additional area to consider is which indicators should be used. There are a variety of endorsed quality and safety measures currently available, some with a stronger evidence base than others, but which ones are best is not clear and will depend largely on local factors. The cost-effectiveness of even the best evidence-based measures and interventions is difficult to prove, and the potential benefits of implementation are likely to vary depending on the local context. The National Quality Forum measures for quality in intensive care serve to highlight some of the difficulties encountered. As of October 2015, The National Quality Forum had endorsed various quality measures for intensive care, including ICU length of stay, venous thromboembolism prophylaxis, in-hospital
mortality, catheter-associated urinary tract infection, and \textit{C. difficile} infection \cite{50}. However, it is informative to note the measures that were previously sanctioned but are no longer authorized. These include severity-standardized average length of stay, the ventilator bundle, central line bundle compliance, and measures of glycemic control with intravenous insulin. Investigators have tried through survey, expert panels, and literature reviews to identify the most useful indicators for measurement in ICUs, often with varying results \cite{51,52}.

Currently, there is no single common safety score card that is appropriate for universal use. As such, the choice of safety and quality metrics for a given ICU needs to be driven by local factors. The selection process should take into account whether the measures are valid rates, whether proportions are sufficient, whether the outcomes being measured are truly preventable with intervention, potential sources of bias, costs of implementation, and the strength of the evidence supporting a given intervention.
INTENSIVE CARE UNIT ORGANIZATION

Providing safe and high-quality critical care has a significant impact on patient safety and quality. Although the vast majority of the literature supports the value of intensivist-based critical care, a landmark study by Angus et al. in 2000 found that more than three-fifths of critically ill patients in the United States are not seen by an intensivist. Moreover, it was estimated that this gap between supply and demand will only widen in the coming decades [53]. On the other hand, many patients in U.S. ICUs are not critically ill and, therefore, are not in need of an intensivist-led care team [54].

Current controversies in this area include: (1) whether round-the-clock intensivist staffing is required for quality care, (2) how many patients an intensivist should oversee care for, (3) whether an intensivist’s role extends beyond the walls of the ICU, (4) whether to employ nonphysician providers and non-intensivist physicians in the ICU, and (5) whether regional intensive care centers and/or telemedicine are useful, safe, and effective.

24/7 Coverage by an Intensivist

Patients become critically ill 24 hours a day, 7 days a week. For this reason, having an intensivist present throughout the night hours is commonplace in Germany (81% of ICUs [55]); however, this staffing strategy is less frequently employed elsewhere around the world (3% of ICUs in the United Kingdom [56], 8% to 15% of ICUs in the U.S. [57–59], and 50% of ICUs in Thailand [60]). The evidence base is still incomplete and when taken together, shows that having an intensivist onsite overnight is not associated with improvements in patient outcomes. Before–after studies of onsite coverage overnight produced conflicting results—one found improvements in standardized mortality ratios whereas the other showed no difference in survival (albeit improvements in complications and ICU length of stay) [61–64]. However, for some, but not others, addition of such providers improved mortality for units with low daytime staffing intensity. A meta-analysis supported this lack of association of nighttime intensivists and meaningful patient outcomes [65]. Other studies found no association with the shiftwork model (including overnight onsite intensivist) and any measured patient outcome [66,67].

Intensivist-to-Patient Ratios
Higher staffing ratios, whether nursing or physician, should theoretically improve quality of care as care providers have more time to spend with each patient. But does the existing evidence support this idea?

In 2005, Dara et al. published a single-center observational study in an academic medical ICU in which the number of patients cared for by each intensivist changed over time from 2001 to 2003. In comparing intensivist-to-patient ratios of 1:7.5, 1:9.5, 1:12, and 1:15, there was no difference in hospital or ICU mortality, although a higher ICU length of stay was seen in patients whose intensivist cared for 15 people [38]. A survey conducted in 2012 by Ward et al. of U.S. Pulmonary and Critical Care Medicine fellowship directors revealed that the median number of patients each intensivist cared for in his/her unit was 13 (interquartile range: 10 to 16), with respondents reporting increased time constraints, stress, and difficulties teaching trainees as patient load increased [68]. Finally, in 2015, Neuraz et al. published a prospective observational study of eight ICUs in which they found that the relative risk of death for ICU patients was 2.0 (95% confidence interval: 1.3 to 3.2) for shifts in which an intensivist cared for >14 patients compared with one in which he/she cared for fewer [69].

In 2013, the Society of Critical Care Medicine concluded that “advocating a specific maximum number of patients cared for is unrealistic,” yet cautioned that care must be taken to recognize the impact of staffing ratios on direct patient care, efficiency of ICU rounds, non-patient care–related activities, and trainee education.

Intensivists Outside the Walls of the ICU

When discussing a safe culture of critical care, it is important to remember that critically ill patients exist outside the walls of the ICU [70–72]. At times these patients are at the onset of their critical illness and, at others, they are awaiting transfer to an ICU—a situation known to be associated with poor outcomes [73,74]. Having an intensivist at the non-ICU bedside of these critically ill patients is a topic which has gained interest of late.

A common form of intensivist outreach is the rapid response or medical emergency team and consultation, which is called when a patient clinically deteriorates outside of the ICU [75]. Although staffing of these teams is inconsistent, many include an intensivist [76–78]. Notably, such teams are being employed more and more frequently in U.S. hospitals [79]. Data about these teams’ impact on patient safety and outcomes are inconsistent [80–83], but, interestingly, satisfaction of ward staff is improved when they are available [84–86].

Non-Intensivist Providers in the ICU
As safety demands consideration of drawing the intensivist out of the ICU, it also mandates consideration of whether it is safe to staff ICUs with providers other than traditionally-conceived-of intensivists. Physician assistants and nurse practitioners have been increasingly involved in the care of ICU patients over the past two decades [58, 87, 88]. Although trained in vastly different manners, it is now possible for both types of providers to specialize in critical care (residency in critical care medicine for physician assistants [89]; acute care track for nurse practitioners [90]), and both providers can assume similar roles in the ICU. Several staffing paradigms have been explored, but a seemingly common one (and one examined in published studies) is the substitution of a nonphysician provider into a role traditionally assumed by house staff of academic ICUs. In several studies comparing a medical ICU staffed with nonphysician providers to one staffed with residents, there was no difference in outcomes, including mortality, length of stay, and discharge destination for survivors [91–93].

More recently, interest has risen in the United States about the use of non-intensivist attending physicians who demonstrate interest and receive training in critical care. In a joint position paper by the Society of Critical Care Medicine and the Society of Hospitalist Medicine, the potential merits of an expedited educational track for practicing hospitalists interested in critical care was detailed [94–97]. Finally, there are now pathways established through the American Board of Internal Medicine, the American Board of Surgery, and the American Board of Anesthesiology for emergency medicine residency graduates who complete a critical care fellowship to sit for the Critical Care Medicine board examinations [98]. Although relatively new, these initiatives designed to train a broader group of attending physicians in critical care will assuredly lead to the provision of safer care to more patients.

Alternative Strategies for Delivering Critical Care

Trained intensivists very likely improve the outcomes of critically ill patients [63, 99], so there are pressures from various stakeholders to increase critical care physician coverage of ICUs. For instance, hospitals wanting to meet the standards of the Leapfrog Group (www.leapfroggroup.org) are required to have intensivists who manage or comanage ICU patients. These intensivists need to be: (1) present during daytime hours and exclusively providing care in the ICU, and (2) able to return pages at least 95% of the time within 5 minutes when not
on site; or be available via telemedicine and arrange for an intensivist or physician extender to be available within 5 minutes. There is, however, a shortage of critical care physicians; thus, not all ICUs can be staffed to these standards [53,57,100].

One potential solution to the critical care workforce shortage is the regionalization of intensive care services in which high-risk patients can be transferred to centers of excellence [101–103]. Such regionalization has already occurred in the care of trauma patients and neonates [104].

It has been shown that the hospital volume of non-surgically mechanically ventilated patients correlates with improved outcomes (i.e., a positive volume–outcome relationship) [105]. Likewise, it may make sense to centralize aggressive life support therapies such as extracorporeal membrane oxygenation (ECMO). Data for widespread use of ECMO as a therapy for severe acute respiratory failure are lacking despite the positive results seen in the CESAR trial, a study in which patients were either randomized to transfer to a single site for possible ECMO or to conventional care at their originating center [106]. The call for ECMO to be studied and regionalized is supported by mixed results using ECMO during the 2009 H1N1 pandemic and a recent meta-analysis demonstrating a positive volume–outcome relationship [107–110]. Although it has been shown that the most critically ill, including those on ECMO, can be safely transported, it is not clear that regionalization is the best solution [111]. Strong data do not yet exist to show mortality benefit for regionalization of ICU services [112].

Intuitively, ICU telemedicine is appealing, and it makes sense that it should improve the outcomes of critically ill patients, but like regionalization, it requires further study [113]. At present, there are some data to suggest that ICU telemedicine improves outcomes in a variety of settings, whereas no data exist to show worsened outcomes [114–117]. Even in a well-staffed critical care system, the addition of a supplementary layer of telemedicine monitoring improved hospital, ICU mortality and length of stay, and adherence to critical care “best practices.” [115]. Despite its theoretical and demonstrated advantages, ICU telemedicine has not been widely adopted. Between 2003 and 2010, the number of U.S. hospitals employing this strategy increased from 0.4% to 4.6%. Most of the expansion was in the first 4 years (101% growth), after which growth plateaued at 8.1% per year [118].
PHYSICIAN TRAINING AND DEVELOPMENT
OF A CULTURE OF SAFETY

It is during residency training that physicians acquire not only their clinical knowledge, but also their familiarity with system-based practice attitudes toward patient safety. Because developing a culture of safety is one of the elements of solving patient safety issues, resident training is central to developing long-term solutions to patient safety problems. However, the ICU experience can be one in which residents themselves become a safety issue. Residents need to acquire the body of knowledge, skills, and experience necessary to function as attending physicians, and as part of this training they need to develop a culture of safety. Yet, lack of supervision, experience, and resident fatigue can adversely affect patient safety, especially in the ICU setting. It is thus useful to separate the issues of safety into those related to proper resident training, which affects the culture of safety in the long term, and those related to resident performance, which impacts patient safety in the short term.

Optimal resident performance requires adequate rest, supervision, and sufficient training to perform increasingly complicated problem-solving tasks. Each of these areas can contribute to safety as they represent potentially latent medical errors (errors due to the design of the educational system as well as the healthcare delivery system).

Fatigue has been associated with altered moods, depression, anxiety, confusion, anger, and most recently, impairment of clinical performance [119,120]. However, extended work hours and exhaustion among trainees were long-standing traditions in medical education and had often been the hallmarks of “excellence” in educational programs. In the past, workweeks of 120 hours and on-call shifts of 48 hours were not uncommon. Fatigue and long hours were likely some of the factors involved in the death of Libby Zion in New York City (http://www.washingtonpost.com/wp-dyn/content/article/2006/11/24/AR2006112400985.html; [121]). Because of this case, New York State instituted duty hour restrictions in 1989, based on the Bell Commission’s recommendations that trainees could not work more than 80 hours per week, or more than 24 consecutive hours. Additionally, new requirements mandated that more senior physicians be present in the hospital 24/7. Responding primarily to public pressure and outside forces and with little high-level evidence, the Accreditation Council for Graduate Medical Education (ACGME) instituted standards which were similar to those of the Bell Commission in 2003, with further restrictions in 2011 [122,123]. Assumptions were made that patient safety and medical
education would benefit from well-rested house staff.

Much of the existing research literature with regard to the effects of work hour restrictions has resulted from the changes implemented by the ACGME, rather than vice versa. A 2004 study found that medical interns made more serious errors in the critical care setting when working a “traditional” work schedule when compared with a work schedule in which extended shifts were eliminated and the number of hours worked per week was shortened [124]. There were concerns, however, about the need for attending physicians to make decisions based on second-hand information provided by covering residents, the need for attending hypervigilance, and compromised house staff education [125,126]. Other studies have either shown no benefit or worse outcomes with institution of the ACGME restrictions [127–129]. A systematic review by the ACGME was inconclusive and called for further high-quality research into the benefits and harms of work hour restrictions [130]. A survey of ICU Directors and Critical Care program directors (Medicine, Surgery, Anesthesiology, and Pediatrics) showed that there was a feeling that the mandated work hour restrictions adversely limited trainee education, professionalism, and patient care [131].

A prospective multicenter trial examining the effects of the ACGME work hour restrictions on surgical outcomes (Flexibility in Duty Hour Requirements for Surgical Trainees [FIRST] trial) demonstrated no variation in death rate or complications between hospitals with strict versus flexible adherence to ACGME rules, as long as total work hour limits were maintained [132].

Even when trainees have sufficient rest, they still require adequate training and supervision. The question becomes how to acquire sufficient experience while minimizing patient risks. Previous paradigms of critical care education have emphasized knowledge acquisition over performance. The most common educational tools in the ICU are teaching at the bedside and formal lectures. Although senior physicians are willing to change their approach to teaching, there are real barriers to innovative education. Clinical workload for attending physicians has increased, whereas resident availability for teaching has decreased, partly because of ACGME-mandated changes, and there is a lack of funding to offset lost clinical revenue for time spent teaching. On this front, attending physicians seem most open to incorporating web-based learning modules and simulations (computer-based and/or with a mannequin) [131].

Simulation can be used to train physicians in the cognitive, procedural,
and problem-solving aspects of critical care. Simulation has been increasingly used as an effective tool for training in medical settings [120]. First pioneered by Edward Leap, who designed a flight simulator for pilots in the 1920s, simulators are used today by all commercial airlines, by astronauts, the military, and the nuclear power industry. Medical simulators today frequently incorporate computers and virtual reality, but it is important to recognize that simulation training does not necessarily imply use of a computer. Simulators have traditionally focused on cardiopulmonary resuscitation models and normal/abnormal heart sounds, but many forms of simulation training are becoming available. Other simulators relevant to the ICU include mechanical models of the airway to teach basic bronchoscopy as well as newer bronchoscopy simulators with virtual reality augmentation [133]. The type of simulator (computer driven, mechanical, or a combination) depends upon the task being learned. For critical care, tasks can be broadly grouped into cognitive tasks (e.g., management of acute respiratory failure and hemodynamic compromise [134]), conflict resolution [135], mechanical procedural tasks (e.g., bag-valve mask ventilation [136], intubation [137,138], bronchoscopy [133], central line placement [139]), and team performance tasks (e.g., respiratory failure using the Anesthesia Crisis Resource Management [ACRM] course [140], Advanced Cardiac Life Support (ACLS) [141]). Simulation has been applied to all three areas.

The incremental benefit of simulation training as compared with standard teaching methods on real-life performance has been demonstrated in only a few studies [132,138,142]. However, there is a much larger body of evidence in which surrogate outcomes (not real-life performance per se) have been used to demonstrate the positive effects of simulation training. Surrogate outcomes from these cases have included measures of student confidence [138] or performance on a model [136–138,141]. On balance, although the current evidence base is still incomplete with only a few randomized trials documenting superior real-life performance after simulation training, it is reasonable to conclude that simulation training will play an increasingly important role in critical care education.

The advantages hypothesized for simulation include safety, efficiency, and availability. Intricate elements and potential complications of difficult procedures, as well as the response to equipment malfunction, can be selectively and repeatedly rehearsed. The ability to provide immediate feedback and team training is also enhanced. Employing simulation models may positively impact direct and indirect costs associated with training and educating personnel through reduced use of operating rooms, and may potentially reduce malpractice claims. It is anticipated that as the expense of such equipment diminishes, simulators
will be increasingly adopted by medical school curricula and for residency training. The American Thoracic Society Skills-based Working Group has formalized recommendations for using simulation as an adjunct to traditional training [143].

The Agency for Health Care Quality and Research has made development of simulation devices and protocols an important priority. At the present time, there is only limited clinical evidence supporting the efficacy of simulators on improving patient-based outcomes such as length of stay and mortality.
REGULATION AND GOVERNMENT IMPACT ON PATIENT SAFETY

The role of governmental and nongovernmental regulation has increased during the past decade and has taken on an international scope. As the public has become more aware of the need for patient safety and quality improvement within healthcare, there have been many new regulatory and reimbursement initiatives originating from the public sector (federal and state governments and agencies [e.g., www.ahrq.com]), state and county health departments, purchasers, nongovernmental organizations (e.g., JC, ACGME), and international organizations (e.g., World Health Organization [WHO]). The hypothesis that significant mortality can be attributed to medical errors has facilitated the implementation of rules and guidelines. Regulatory efforts encompass rules and regulations, but also accreditation of organizations, certification of providers, and reimbursement programs based on patient safety processes and outcomes.

The CMS has adopted pay-for-performance reimbursement models [144] and non-reimbursement strategies for complications of care-related to specific “never events” [145]. Appropriate levels of regulatory oversight of patient safety research that ensures patient protection must be balanced against the need to acquire new knowledge necessary to improve patient care in the ICU [146]. Many regulatory initiatives seek to improve outcomes, but others may risk causing confusion and malaise for healthcare providers as they attempt to comply with conflicting rules, mandates, and guidelines, and thus may actually become impediments to patient safety. For example, national guidelines for sepsis management were recently incorporated into the CMS inpatient quality reporting requirements (posted QualityNet April, 2015). This spurred significant comment from the critical care and emergency medicine communities, given the rapid adjustment of guideline recommendations. As has been suggested, protocols that mandate certain physician behaviors may adversely affect diagnosis, antibiotic choices, utilization of invasive procedures, and consumption of critical care resources [147,148]. Two important trends are greater collaboration for developing safety efforts between relevant organizations and the emergence of international partnerships among regulatory organizations. These efforts may result in improved harmonization of standards and regulations.

In regard to physician-related accreditation and certification, the ACGME has included patient safety concerns in its resident program accreditation process, both when mandating duty hour limitations and
for requiring the inclusion of patient safety in educational curricula. Likewise, the American Board of Medical Specialties requires evidence of practice improvement efforts for maintenance of certification. Regarding organizational-level regulations, the JC publishes an annual update of its national patient safety goals in support of their standards for accreditation, which include ICU-related processes of care [149]. In 2005, the JC and Joint Commission International were designated by the WHO as the first members of the WHO Collaborating Centre for Patient Safety Solutions. The Collaborating Centre has organized an international network to identify, evaluate, adapt, and disseminate patient safety solutions (http://www.ccforpatientsafety.org/WHO-Collaborating-Centre-for-Patient-Safety-Solutions-continued/). This effort demonstrates the international intent to create links between key organizations and individuals with expertise in patient safety (accrediting bodies, national patient safety agencies, professional societies, and others).

Independent, not-for-profit organizations, such as the Institute for Healthcare Improvement (IHI), develop programs to accelerate improvement by promoting cultures for change, stimulating promising concepts for improving quality and safety, and assisting healthcare organizations to implement these new concepts. The IHI has had considerable influence on regulatory organizations with respect to adoption of IHI initiatives, such as ventilator bundles, central line bundles, sepsis bundles, intensivist staffing models, and rapid response teams (http://www.ihi.org/IHI/Topics/CriticalCare/IntensiveCare/Changes/IntensiveCareChangesIndex.htm). Because of the emphasis on swift promotion of promising new interventions, such organizations have occasionally endorsed interventions (such as tight glycemic control) prematurely, ahead of supporting evidence.

Other proposed areas of regulation include minimum nursing staffing ratios to meet workload demands [150] for Medicare-participating hospitals and limitations of excessive work hours for nurses and residents. Hospitals have been required to implement specific improvements and to develop a program for quality assessment. The IHI has also suggested that a patient safety officer needs to be an important component of all large healthcare organizations [151].

Safety is an increasingly pressing concern in the high-risk environment of the ICU. There is ongoing implementation of integrated and coordinated systems that identify patient safety problems and report them back to providers. Such systems can improve performance of the
ICU as well as “their structure, processes and outcomes of care.” ICU reporting systems identify trends and patterns that facilitate healthcare improvement and reduction in preventable medical incidents. Because safety and error prevention in the healthcare setting compares unfavorably with those of other industries, a major thrust has been to adopt strategies and technologies that have proved successful in other settings and to apply them to the ICU. Continuing to establish common definitions of healthcare-related safety concepts as well as systems for safety monitoring and reporting will improve individual and group capabilities, thus improving patient safety. Approaches that have been implemented to some extent in the ICU community include incident reporting, targeted monitoring of process of care and discharges, trigger tools and ICU audits. Integration of electronic ICU patient data—such as hospital admissions information, laboratory results, progress notes, imaging, and authentication data—with non-ICU patient data across a hospital’s computerized medical record is a prerequisite for promoting patient safety. ICU organization and staffing models [152], team training efforts [153], and programs in critical care telemedicine all impact safety for the ICU and continue to be studied. Hospital and ICU designs, emphasizing patient and staff safety, as well as a focus on ICU location within the hospital (i.e., placement of the ICU adjacent to emergency departments and surgical suites to facilitate rapid transfer of unstable patients), and new informatics systems that electronically distribute filtered and targeted smart alarms will come under increasing review. Although regulation by public sector agencies will impact the safety of the critical care environment, developing a culture of safety through graduate and postgraduate medical education may prove to be even more important in achieving substantive and long-lasting quality improvement for critical care.

During the last four decades, critical care has matured to a distinct medical specialty. Sepsis, respiratory failure, and the care of the complicated postoperative patients are now perceived as the purview of the intensivist. Concomitant with this evolution of critical care medicine has been a growing focus on health care outcomes. This emphasis on the end points and effects of medical care generally, and critical care specifically, reflects the realization that critically ill subjects face a high risk of death and that many interventions applied in the intensive care unit (ICU) are expensive. Some older studies estimate that nearly 1% of the gross national product of the United States is consumed in the ICU and, relative to days spent on hospital wards, others suggest that ICU costs are nearly three times greater [1,2]. More recent investigations suggest that less of the GNP is spent on ICU care, but concerns with the expense of ICU care continue [3].

Whether it is mechanical ventilation (MV), extensive nursing care, or acute dialysis, many of the technologies and medications used in the ICU are associated with substantial economic costs. In addition, some believe that ICU interventions only delay mortality rather than prevent mortality, or that mortality reduction in the ICU comes only at the price of significant morbidity. Thus, there is increasing pressure to carefully evaluate and to understand the results of ICU care. This pressure becomes even more evident when one considers that ICU outcomes must
be evaluated from both patient and societal perspectives. In other words, the emphasis on outcomes in the ICU reflects an underlying question about value. In that vein, outcomes research reflects a systematic effort to address these issues and concerns. According to a position statement on outcomes research in critical care, “Outcomes research is employed to formulate clinical practice guidelines, to evaluate the quality of care, and to inform health policy decisions” [4]. Like clinical critical care, outcomes research draws on many different tools and expertise in multiple disciplines.

More than only an issue of economics, outcomes research requires expertise in psychology and anthropology (to understand patient and physician behavior), epidemiology (to identify disease patterns and burdens), and health services research (to appreciate process) [4]. Use of a term like outcomes, though, presupposes a question: Outcomes for whom? At the bedside, the clinician or the investigator focuses on pathophysiology of a sole patient. Outcomes research also addresses broader issues. Rather than being either centered on a particular disease or a physiologic measure, outcomes research deals with the overall results of care for the patient, for the family, and for society. Also in distinction to traditional clinical research, outcomes research has clear policy aspects as well; it attempts to facilitate debates about competing plans for resource allocation, research priorities, and national health policy. As an example, a randomized clinical trial deals with issues of efficacy (Does intervention “x” in a controlled environment have an independent impact?) and outcomes research is more concerned with effectiveness (What are the implications of intervention “x” applied outside a controlled setting and in the “real world” for the patient and society?). Traditional clinical research, moreover, often employs the experimental approaches, and observational methods that are routinely used in outcomes research.

In short, outcomes research attempts to use methods from the social sciences to augment the understanding of health care as opposed to using only methods from conventional “hard” sciences. As a recent summary regarding outcomes research for sepsis indicated, the outcomes researcher seeks to answer a question separate from traditional research [5]. The clinical investigator essentially asks, “Does this work?” and outcomes researchers deal with the concern, “Does it help?” [5]. Readers should note that outcomes research is now a key component of the biomedical enterprise. It is no longer seen as an option or an add-on. It fits with mechanistic and clinical work in building the triumvirate of information needed to translate research findings into clinical practice. The absence of outcomes studies can lead to the failure to adopt what otherwise might be useful interventions. The most recent policy example of the import of outcomes research in the United States is the efforts by
the Centers for Medicare and Medicaid Services (CMS) to drive quality by altering hospital and physician reimbursements. This initiative, known as Value Based Purchasing, is a broad effort to enhance quality throughout the hospital. However, many of its components deal with issues directly related to ICU care. Concurrently, the federal government has now funded the Patient Centered Outcomes Research Institute (PCORI). PCORI was created as part of the Patient Protection and Affordable Care Act to help fund and lead research into comparative-effectiveness so that patients and clinicians can make better choices.

METHODS IN OUTCOMES RESEARCH

Outcomes research relies on multiple methods for exploring patient-centered concerns. Generally, researchers employ both qualitative and quantitative methods [4]. Qualitative approaches offer insight into complex processes that do not easily lend themselves to standard hypothesis testing. As such, qualitative work often results in the generation of important hypotheses for more formal testing. In other words, qualitative works, such as surveys of patient preferences, can form the foundation for quantitative modeling. Quantitative methods are more standard for outcomes research in critical care and have two general aspects. First, they use some tool to measure a particular outcome (e.g., mortality, quality of life, functional status, costs). Second, quantitative techniques then seek to compare the outcome of interest between at least two alternatives. Unlike the controlled environment of the bench laboratory or even the randomized controlled trial (RCT), outcomes research is necessarily exposed to multiple potential confounders that can and do affect the primary measure of interest. Because critical care outcomes research remains patient-centered, it is important to acknowledge that these subjects bring with them complexities that may alter their mortality, quality of life, and function. Moreover, the impact of these preceding factors may affect a researcher’s end point of interest in ways that have little to do with the intervention under study. Similarly, after any intervention in the ICU, many post-ICU variables come into play that might affect the results of an outcomes study.

To address these complexities requires adoption of various techniques, all of which must be rigorous and reproducible. Therefore, outcomes research has relied on more than RCTs. RCTs are well suited for deciding if specific interventions or agents can alter an easily ascertainable end
point such as mortality. For example, use of large sample sizes combined with both block randomization techniques and protocols for patient care help to ensure that the potential confounders previously noted are minimized and, in turn, allows one to explore questions such as how low tidal volume MV affects mortality at day 28. But if the policy or research query deals with the functional status or total cost of care for survivors of acute respiratory distress syndrome (ARDS) more than a year after their hospital discharge, one may require additional approaches. In any event, critical care outcomes research begins by defining a particular question. The investigator can subsequently determine which approach is most appropriate. In fact, sometimes outcomes research requires entirely separate study designs and major modifications to traditional models of clinical research or a combination of approaches. In other cases, more traditional models of investigation can be expanded to incorporate outcomes measures. This generally requires building these measures into the trial during the study inception phase. Currently, this is often done so that data needed for understanding the costs or societal implications of an intervention are gleaned at the same time as a primary trial is underway. This approach also facilitates the collection of information desired and often required by payers prior to decisions about coverage and reimbursement for novel therapies. Hence, outcomes research represents an extension and complement to standard research practices.

The advent and diffusion of electronic health records (EHRs) has fostered outcomes research generally. EHRs represent a rich source of data that can be examined as part of many research efforts, irrespective of methodology. The data captured in EHR can allow investigators to track patients, their resource use, and their outcomes across many transitions of care, while also providing information about multiple components of that care. The increasing reliance on EHRs also makes it simpler for investigators to amass significant amounts of data on larger cohorts of patients with relative ease. The larger sample sizes and more extensive data that one can glean from EHRs have made the EHR a major resource in outcomes research.

**Observational Studies**

Of the various types of observational studies (e.g., case series, case–control, cross-sectional, and cohort), two are particularly important in critical care outcomes. A cross-sectional design has the advantage of looking at one precise time or over a short period of time at a specific disease or practice. This snapshot-in-time approach can provide important insight into both epidemiology and aid health services research. For example, a recent 1-day international survey of respiratory failure in the ICU demonstrated the burden of this syndrome relative to
other diseases treated in the ICU and also documented the wide range in practice style with respect to the use of MV [6]. The Sepsis Occurrence in Acutely Ill Patients (SOAP) study, a European sepsis registry using an essentially cross-sectional design (it covered a set 2-week period) confirmed the burden of sepsis in the ICU and underscored the variability in the use of various medical therapies in the care of these patients [7]. Hence, these cross-sectional analyses generated important information about the current state of affairs and therefore provided a potential benchmark for use in future comparisons. Cross-sectional studies also serve to provide important benchmark data so that changes over time can be more easily assessed. As an example, Esteban and coworkers [8] completed a similar point prevalence survey regarding the need for MV and were able to show how outcomes were improving over time via a cross-sectional study design.

In addition, cohort studies are valuable components of outcomes research. With this strategy, subjects are selected based on some common exposure (e.g., a diagnosis, a risk factor) and then observed [9]. Thus, cohort analyses may have the advantage of being prospective as compared to cross-sectional analyses. Cohort studies also specify a set starting time for the observations (e.g., time zero) from which observations proceed forward. Researchers can then look at the interplay of certain predefined risk factors or interventions and the characteristics that defined the cohorts to see how these affect the outcome. Often a cohort design is used either to describe the natural history of a disease, to assess quality of life, or to capture the real world outcomes associated with certain interventions/therapies (as opposed to what might be gleaned in the strictly controlled environment of a randomized trial). Although theoretically straightforward, cohort studies pose important challenges for the researcher. Selection bias and the inherent heterogeneity of critically ill patients can confound efforts to create a homogeneous cohort. Similarly, one needs to ensure means for capturing multiple potential exposure variables and acknowledge or model interaction between risk factors, exposures, and time which is complex when there are multiple confounders.

As Needham et al. [9] and Dowdy et al. [10] indicate in a review of methodologic issues associated with cohort studies, this study design has three key components: subjects, outcomes and exposures, and time. Subjects must be carefully identified, but the cohort study gives the researcher flexibility to define the population as sharing particular characteristics, such as common diagnoses, or risk factors. Alternatively, cohorts can be developed such that two groups emerge: individuals exposed to a particular event or variable and those not exposed. As a result, one can, using this technique, begin to draw conclusions about causal relationships. Generally, because the cohort shares some common
time of designation (e.g., time zero) by observing the population one can evaluate the strength of the relationship between the given exposure and the outcome. Unlike the rigidity of an RCT, in which randomization works to ensure study groups are similar except for the intervention in question, a cohort design provides the researcher the opportunity to explore multiple exposures simultaneously, and how they interact with each other. To the point, in an RCT of a novel treatment for sepsis, any differences seen in outcomes should be a function of the particular intervention experimentally introduced, provided that randomization worked. The ICU organization, pre-ICU care, and posthospital events should not affect the outcome because randomization should ensure that the impact of these variables is equalized between the active and comparator groups.

The purpose of a cohort study is to enhance the RCT by providing information that cannot, by definition, be gleaned from the RCT. The caveat, of course, is that cohort studies are prone to confounding and may lack generalizability. Nonetheless, expanded adoption of cohort studies can also facilitate better understanding of natural history by shifting the focus back to a time prior to ICU admission. Without some initial work via a cohort approach, we face challenges when addressing significant questions relating to what determines which patients get admitted to the ICU, who most likely benefits from ICU care, and the outcomes for those never admitted to the ICU. Most importantly, cohort studies allow researchers to identify potential patterns and relationships which can suggest causal connections, and, which in turn, can serve as the foundation for future randomized trials. As an example, the initial work on the impact of delirium on ICU outcomes all derived from cohort work and then became the foundation for multiple subsequent interventional trials [11].
Unlike traditional biomedical research, which looks at either novel technologic interventions (new drugs, new devices) or perhaps management strategies, the interventions studied in outcomes research are more diverse. Certain clinical measures have significant outcomes implications for the patient and society. However, managerial and organizational changes may be equally important. The issue of management and organization of critical care services is particularly acute at present, given current (and conflicting) data suggesting that the model of ICU administration affects both mortality and cost \([12,13]\). The question of organization and management is broader than simply whether one uses a closed, full-time intensivist model or a more traditional open ICU model. Under the rubric of organization and management are questions of nurse-to-patient ratios, the role for respiratory therapy, assessments of the impact of a dedicated critical care pharmacists, and the significance of and adherence to protocols and bundles in the care of the ICU patient. Measuring how these types of potential features of the ICU work and whether they help patients and society is perhaps as important a question as if a new molecule for sepsis alters mortality. Issues of management and organization can provide feedback to affect the conduct of traditional research. Whether it is studies of resuscitation strategies or rapid response teams, these types of interventions include service, delivery, and organizational aspects. If any one of these components of the trial collapses, the entire venture may be jeopardized.

**Mortality**

With respect to end points, mortality remains the center of investigative efforts because it has tangible meaning to the patient, to health care institutions, and to society. When outcomes research addresses mortality, it tries to do it in an appropriate context. In other words, the question of mortality begs the question of when? Is the appropriate timeframe survival to ICU discharge or to hospital discharge? Are these time points too myopic? Altering long-term mortality (e.g., 2 years after ICU admission) would be an admirable goal. Historically, 28-day all-cause mortality has served as the primary end point for trials in critical care. However, after some period of time it seems reasonable to postulate that occurrences and interventions in the ICU diminish in their impact while
the patient’s age [14] and health state prior to his or her ICU admission become the main drivers of outcomes. Thus, the issue revolves around the timeframe chosen for measurement and its likely mechanistic link to the intervention under evaluation [15].

It is important to be cautious, though, since one can artificially alter ICU mortality by early use of certain interventions (e.g., tracheotomy in order to facilitate transfer to a chronic ventilator care facility). Likewise, decisions about when to suggest withdrawal of care can alter the apparent timing of death in the ICU. The central limitation is that with all time-dependent end points, there can be confounding by multiple factors. As the recent American Thoracic Society position statement on outcomes research appropriately observes, “The ‘correct’ mortality endpoint depends on the specific research question, the mechanisms and timing of the disease and/or treatment under study, and the study design” [4]. In addition, if a disease state is not associated with significant mortality, use of this measure may simply fail to capture the value of a particular intervention. Finally, mortality as the sole end point of any research ignores the entire concern about morbidity and the tradeoff between mortality and morbidity. Focusing only on mortality fails to address the quality of life of the survivor and misses the potential for survival to be rated by some as even worse than death.

Mortality, moreover, has limitations as a tool for comparing outcomes across different ICUs. Although recorded and tracked nearly uniformly among ICUs throughout the world, ICU mortality is a relatively uninformative measure of ICU performance. Extensive variability exists in not only the types of patients admitted to different ICUs but also in admission and discharge policies [15]. Some ICUs serve as major referral centers for and receive multiple transfers from other hospitals. These patients tend to be sicker or in need of specialized care. Hence, the mortality rates of the ICUs that send these persons elsewhere may be artificially low compared to the ICUs that accept such high-risk cases. Similarly, ICUs with intermediate-care facilities can transition individuals out of the ICU at different rates than ICUs lacking access to these resources. This fact can alter apparent ICU mortality rates because one might essentially be able to transition patients receiving comfort care only out of the ICU so that when they die the death is not captured as an ICU-related event.

One could correct for these possible variables by employing a definition of ICU mortality (for benchmarking performance) that removed transfers from both the numerator and denominator of the crude mortality rate. Adjusting for differences for availability of “stepdown” wards can be made by limiting comparisons to like-sized hospitals. However, even these efforts would be insufficient for purposes of performance and quality assessments because issues of case-mix remain unaddressed.
Case-mix as a concept tries to capture that different ICUs admit different types of patients with differing severity of illnesses. It is important to note that case-mix as a concept describes more than differences in disease severity [16]. Case-mix adjusting tries to balance issues with underlying diagnosis, comorbidity, age, and severity of illness [16]. To illustrate the breadth of the aspects related to case-mix, one need only consider an ICU that cared for only postoperative cardiothoracic patients should report low mortality rates and an ICU that admitted mainly immunocompromised persons would certainly describe different outcomes, even after one adjusted for severity of illness. As a corollary, comparing mortality between similar types of ICUs that admit similar types of patients, after controlling for disease severity, can prove helpful and identify potential outliers which require further investigation [16].

Severity of Illness Tools

To address disease severity, multiple tools exist. They differ with respect to the variables they measure, when they measure these variables, and if they try to describe ICU mortality or hospital mortality. The Acute Physiology and Chronic Health Evaluation (APACHE) score is commonly used in the United States and the Simplified Acute Physiology Score (SAPS) system is more regularly employed in Europe [17–19]. Severity of illness scores has been developed for application to specific types of patients (e.g., pediatrics, trauma) and others try to deal with a broader range of subjects. Other modeling systems include the Sequential Organ Failure Assessment (SOFA) score and the Multiple Organ Dysfunction Score [20,21]. A major limitation of all scoring systems is that they are developed and validated on large patient populations. Therefore, predicted mortality estimates for individual patients cannot and should not be translated into decisions at the bedside as to whether, based solely on predicted mortality, one should withhold or offer aggressive care. This is also true with severity of illness and prognostication tools developed for use in specific disease states that may require care in the ICU, such as the Pulmonary Embolism Severity Index (PESI) or scores developed to examine outcomes after ARDS [22,23].

Another concern with severity of illness tools as they relate to mortality is that some were initially created many years ago. Over time, new interventions and technologies have altered patient care and mortality. Hence, older iterations of certain models may no longer apply and no longer have adequate calibration to be informative. Like many scales,
they require recalibration. As an example, the APACHE system is now on its fourth revision, and with APACHE II versus APACHE IVa, there are significant differences in terms of the explanatory power [24]. Nonetheless, in critical care research, many have adopted the APACHE II and III approach as its equations are published and free available (APACHE IVa remains proprietary and subject to purchase). Researchers and administrators need therefore be cautious when assuming that similar scores computed by an older rubric necessarily translate into similar predicted mortalities among populations or across ICUs. APACHE generally functions by exploring historical cohorts of patients and creating prediction scores based on this “control” population. Alternatively, one can also use the acuity measures used for these instruments to derive from predictions that are specific for the population of interest or under study.

Calculations of the actual scores for patients can also be prone to error. Several studies document significant interobserver variability among even trained researchers as to the calculation of severity of illness scores [25]. With APACHE II, one project revealed that the interrater agreement was strikingly poor ($\kappa = 0.20$) [26]. The main sources of variability appeared to be in assessment of the Glasgow Coma Score, but variability was evident even for the determination of the blood pressure. Changes in practice can also have unpredicted effects on severity of illness scores. Nearly all scoring systems rest on measurement of physiologic parameters such as blood pressure, platelet count, and hemoglobin. The more extreme the actual value from the “normal” range, the greater the negative impact of this factor on the individual’s composite severity of illness score. As an example, low hemoglobin in the first 24 hours after ICU admission is associated with more APACHE II points than normal hemoglobin. Clinicians, though, may now be more tolerant of lower hemoglobin than they were when APACHE II was created. In fact, a restrictive transfusion strategy that necessarily allows the hemoglobin to drift lower may improve outcomes [27]. Consequently, APACHE II scores among ICU patients could rise over time, owing to changes in practice. This increase in APACHE II-predicted mortality when actual mortality might improve because of a change in clinical practice based on a large randomized trial underscores a significant assumption and limitation of severity of illness scoring classifications.

Severity of Illness and Performance Assessment

Mortality prediction equations can also result in calculation of a standardized mortality ratio (SMR) [15]. This ratio compares observed mortality to predicted mortality. Conceptually, the SMR can be calculated irrespective of the severity of illness system used to determine the
predicted mortality. Ratios greater than 1 suggest excess mortality and those less than 1 imply enhanced survivorship. Implicitly, an SMR greater than 1 indicates an ICU with inferior outcomes after adjusting for severity of illness case-mix. Alternatively, though, differences in SMR can reflect more than quality. First, scoring systems may be generally imprecise (see previous discussion) and may not capture some aspects of disease severity or other case-mix issues. Second, the SMR can be affected by the quality of data collection and by the sample size. If the data collected is biased, then the calculations of predicted mortality may be incorrect. Likewise, if the sample size is small, the estimated confidence intervals around the SMR may be so wide as to reinforce the notion that the ICU in question is performing as predicted when there is a great likelihood that it is not. There is also discordance in the published literature exploring if and how well the SMR correlates with other markers of ICU quality. Some investigators suggest that the SMR sufficiently captures aspects of quality and others conclude that the relationship between other markers of quality and the SMR is less clear [15]. It is likely that no one SMR calculation method accurately reflects quality. Therefore, as policy makers, third-party payers, and patients demand simple report cards that allegedly capture quality, it is important that the intensivist resist the urge to simply publish SMRs without references to case-mix. Some more recent scoring systems address this (i.e., APACHE IVa) but still may be imprecise as they derive from periodically updated historical cohorts. We need to encourage the use of multiple measures beyond the SMR to describe qualitative differences in ICUs given these limitations of the SMR.

Nevertheless, the SMR can be used over time to assess interventions within an ICU or group of relatively homogenous ICUs [15]. Although one may not be able to conclude that SMR differences across institutions reflect true differences in quality and performance, when used as a benchmarking tool the SMR can be insightful. If one ICU has historical data about its case-mix and performance, it can then track over time how the SMR varies in response to interventions. Conversely, an increasing SMR can suggest the presence of some change in practice or structure that is adversely of positively affecting mortality. By identifying these trends and investigating them, ICU staff and administrators can elucidate potentially harmful or helpful changes that have transpired and attempt to address them.

The key limitation relating to the use of the SMR rests on the endpoint chosen. Is mortality to be measured at the ICU level or at hospital discharge? Again, as noted above, various models are calibrated for different time points. Calculating the SMR for the entire hospitalization with a tool designed only to look at ICU mortality can lead one to reach faulty conclusions. Several investigators have documented that if one
looks at an SMR for only ICU events as opposed to all in-hospital deaths, one can reach vastly different conclusions about the relative quality of various ICUs [28-30].

**Organ Failures**

One effort to move beyond mortality as the primary outcome measure for critical care has been the evolution of the concept of organ failure-free days [3]. The free-day paradigm recognizes that reducing mortality in the ICU may not always reduce morbidity. In fact, reductions in mortality may only increase morbidity by keeping alive for several additional days patients who otherwise would have died but then, nonetheless, succumb to the acute illness. From a different vantage, some interventions may appear attractive on a superficial level because they decrease the duration of either MV or vasopressor support. However, a shorter duration of MV in one population may only reflect a higher death rate in that cohort. In other words, there is a competing impact of mortality in the assessment of such time-to-event (e.g., liberation from MV) phenomena.

These two facts promoted the development of the “failure-free” day paradigm. As a consensus conference on sepsis stated, this concept evolved out of a need to evaluate “the net effects of therapy” and to try to “integrate mortality with morbidity” [3]. Failure-free days are computed so that each day alive free of the organ failure in question is counted during the specified observation period. If a patient dies before the study termination or requires support beyond this time point, he or she is assigned 0 failure-free days. Historically, failure-free days are measured up to day 28 following the start of an investigation. The 28-day cutpoint, however, is arbitrary and reflects that most trials in critical care use the 28-day mark as the final date for ascertaining vital status. One could follow subjects out further if there were a biologically plausible reason to believe that the intervention under analysis could have an impact to that time point. As an example, if one were interested in MV-free days accrued during the 28 days following a patient’s enrollment in a study and the patient died on day 7 while still on MV, he or she would be credited with no ventilation-free days. If the individual required 7 days of ventilation and was alive at day 28, he or she would have earned 21 MV-free days. If remaining on the ventilator for all 28 days, no ventilator-free days would accrue.

The failure-free-day approach has the potential advantage of capturing morbidity that transpires outside the ICU, such as the need for continued
dialysis, as it is organ system–specific rather than defined purely based on the subject’s location of care. It can further account for shifts in a patient’s clinical status that might not be measured accurately if a researcher only recorded mortality. A patient with chronic obstructive pulmonary disease, for instance, might require 2 days of ventilatory support initially, be liberated from MV, but then several days later deteriorate and need to be placed back on ventilatory support. This waxing and waning clinical status can potentially be accurately described from an outcomes perspective with the use of ventilator-free days.

Is it appropriate to pool death with requiring 28 days of MV but still surviving? The fundamental struggle in this question illustrates why organ failure-free days can only be used as an adjunct to other measures of outcomes in critical care. It is certainly not clear that organ failures correlate with meaningful clinical outcomes or if surviving 28 days on a ventilator with a respiratory organ failure is comparable with death. On the other hand, the concept of organ failure-free days allows one to examine if and how a novel approach or therapy might accelerate recovery. In turn, it lays the foundation for the use of pooled end points in clinical trials in critical care. If mortality remains the only primary end point for studies in critical care, then investigators may fail to pursue options that may prove valuable in other ways. The organ failure-free-day concept also allows one to capture the effect of interventions on markers of resource utilization and cost. Differences in the use of ventilation, dialysis, and vasopressors have important implications for patients. Simultaneously, because of the costs associated with these interventions, decreasing organ failures and morbidity has ramifications for health care institutions, third-party payers, and policy makers. Future work in this area may in fact move beyond organ failure and try to develop metrics that incorporate this with mortality into a form of quality-adjusted survival measure. At present, the concept of the organ failure-free day is often recorded as a secondary endpoint in trials of dealing with sepsis, pneumonia, and respiratory failure. However, because of the issues noted above, it generally is not considered sufficiently robust to serve as a primary endpoint.

Health Status

From the patient’s perspective, surviving the ICU raises many issues. Most patients will require some additional time for further recovery along with the potential need for rehabilitation. Moreover, some physical impairment persists after ICU care, and this impairment can affect functional status, mental health, and quality of life. Globally, each of these concepts (functional state, mental health, quality of life) all attempt to capture the concept of health status. The need for adequate
assessments of health status is made more acute given the limitations of a sole focus on mortality.

Readers should note that, although the concepts are intertwined, functional status (either physical or mental) is distinct from quality of life. Functional status depicts the subject’s capacities; in contrast, quality of life attempts to gauge an individual’s satisfaction and state of well-being. As a result of this subtle distinction, someone who has a major functional limitation may rate his or her quality of life as high while another patient with relatively minor limitations might describe his or her quality of life as poor. Moreover, quality of life essentially relies on using the individual as his or her own control even if the plan is to eventually compare quality of life between patients. Persons are asked to rate their quality of life relative to what they perceive it was prior to needing ICU therapy. Functional status, on the other hand, generally measures capabilities relative to a fixed scale of performance that is set irrespective of what the person’s prior functional status might have been. As such, functional status tends to be more objective. Quality of life, alternatively, is influenced by a person’s values, perceptions, and preferences [31]. Quality of life is also measured in a social context. Assessing an ARDS survivor’s lung function provides no insight into how having physical limitations after surviving ARDS alters one’s interactions with their family and friends.

Functional status captures physiologic assessments of impairment along with global and mental/neuropsychologic performance. Early outcomes studies after critical care and functional status explored the long-term pulmonary complications of ARDS [32]. Researchers examined how gas exchange and radiographs varied over time in ARDS survivors. Other investigators have used general measures of functional status to describe survivors of ICU care [32]. Often-used tools for this include the 6-minute walk test and the activities of daily living (ADL) system. ADL assessments as a tool have the advantage of being widely familiar to clinicians and easy to implement. Some, though, question their applicability to critical care outcomes [32]. ADLs may be of limited value because they were developed specifically for the elderly. Young survivors of critical illness may recover to a state of function beyond what the ADLs generally capture. The information that does exist indicates that severe functional impairment results following ICU care and that it may resolve slowly. For example, Herridge et al. [32], in a prospective observational analysis of ARDS survivors, noted that only 50% had returned to work by 1 year and many reported persistent limitations of their ADLs.

Evaluation of cognitive impairment complements appraisals of functional status. Again, because of the difficulty in assembling cohorts of critical care survivors, the heterogeneity of these patients, and the lack of validated tests appropriate for ICU survivors, limited information exists
regarding this as an outcome parameter. In a comprehensive review of this issue, Hopkins and Brett [33] reported that at 1 year, nearly a third of ARDS patients had cognitive limitations. A more recent study of a cohort of 51 ICU subjects suggested that 35% of these subjects scored at or below a level similar to the lowest fifth percentile of a normal population [34]. However, over time, 95% had experienced significant improvements of cognitive function [34].

The implications of persistent cognitive impairment are significant because they may portend difficulties with future employment and return to work. Hence, improved evaluations of cognitive recovery after critical illness in clinical trials, and the time course of that recovery, may help identify interventions that can have major implications for our patients. Again, if not incorporated into outcomes research, one cannot determine if and how ICU care affects this variable. Likewise, it seems that different approaches to care in the ICU can alter neuropsychologic recovery from critical illness. Specifically, posttraumatic stress disorder (PTSD) is an emerging concern in outcomes research. The incidence of PTSD following an ICU course is unknown, but some survivors report disturbing memories and meet the clinical criteria for PTSD. Outcomes researchers have linked the development of PTSD to previous delusional memories while hospitalized, suggesting that our approach to sedation during the acute phase of a subject’s illness can affect the rates of PTSD [35]. Confirming this, Kress et al. [36] observed that the incidence of PTSD approached 33% in persons randomized to standard sedation practices in the ICU and there was no PTSD in those allocated to a strategy relying on a daily interruption of sedation. The strongest evidence documents the significance of PTSD on patients, and thus ICU outcomes, derives from work that describes the “post-sepsis syndrome (PSS).” PSS describes a range of various impairments neurocognitive and other impairments that substantially affect post-ICU recovery and functioning. For example, beyond PTSD, many patients may suffer from cognitive impairments which specifically relate to higher-order thinking and executive functions. Depression and anxiety also are prevalent among ICU survivors [36].

Quality of Life

In distinction to functional parameters such as the 6-minute walk distance or even cognitive function, estimating quality of life poses several unique challenges. Determining both the validity and reliability of quality-of-life measures, for example, is difficult. In addition, quality-of-life evaluations represent an intersection of clinical science with social
science because many of the tools for rating quality of life rely on psychometrics for their theoretical foundations. Furthermore, the results of quality-of-life determinations can be affected by who is asking the questions and how they are asked. Research documents clearly that a patient and his spouse may score the patient’s quality of life differently.

In general, quality-of-life tests attempt to score this on some form of a scale, which may be either continuous or categorical. The survey tool itself is often composed of select items that ask about certain aspects of life, functionality, quality, and so forth [37]. Items that inquire about certain, specific categories or aspects of quality of life are considered to fall within the same domain. Examples of domains routinely used to classify quality of life include pain and impairment, functional status, social role, satisfaction, and death (as death may be viewed by some as worse than surviving). In reporting the results of quality-of-life testing, both aggregate scores and scores within a certain domain may be reported. The aggregate score often gives a sense of the overall health-related quality of life. Breaking out scores across the various dimensions can presents a profile of how an illness impacts different aspects of quality of life. In addition, two distinct types of quality-of-life data are regularly collected: health profiles and utility measures [37].

In contrast to quality of life measures, utility measures represent the preferences of groups of individuals who share certain common characteristics, such as exposure to like treatments or similar underlying disease states. Quality-of-life scales may be either generic or disease-specific. Generic scales, such as the Sickness Impact Profile (SIP) or the Short-Form 36 (SF-36), have been developed in large diverse populations so that normal values are available [37]. Using these types of instruments allows comparisons across multiple disease states and various populations. Disease-specific instruments, such as the St. George’s Respiratory Disease Questionnaire, may be better calibrated to detect changes over time as they focus on only one disease state or organ system [37]. These disease-specific measures are also focused on aspects of quality of life that may be of most concern to that specific group of patients. In other words, there is a tradeoff among rubrics between generalizability and resolution. Therefore, understanding critical care outcomes and ICU care’s impact on quality of life necessitates studies using both approaches. Examples of various quality-of-life measures are shown in Table 135.1.

Despite using differing tools, examination of different types of patient cohorts, and issues with follow-up evaluation, most quality-of-life research indicates that this is substantially impaired initially in ICU survivors. For example, Tian and Miranda [38] evaluated more than 3,500 ICU patients 1 year after initial admission. Employing the SIP, they observed that scores were substantially reduced among survivors. The main source of the impairment in quality-of-life assessment arose in the area of physical functioning. Interestingly, there was no correlation between the extent of the limitation of quality of life and either severity of illness at ICU admission or the duration of stay in the ICU. Others have confirmed this observation that severity of illness does not explain the limited quality of life reported by some persons. In a cohort of elderly survivors of prolonged MV, Chelluri et al. [39] observed that initial severity of illness as measured by the APACHE III score failed to explain both subsequent functional limitations and lower quality-of-life scores during the year following ICU discharge. Using the SF-36 rather than the SIP, Heyland et al. [40] concentrated on sepsis survivors. Compared to the general U.S. population, scores were significantly lower for nearly all domains. Both physical functioning and social functioning were rated at
approximately two-thirds the level noted in a general U.S. sample. However, when analyzed against a cohort of subjects with chronic disease such as either chronic obstructive pulmonary disease or congestive heart failure, the self-reported quality of life of sepsis survivors was similar.

More recent studies have explored how quality of life changes over time after ICU discharge. Most surveys of quality of life represent cross-sectional efforts measuring this at only one time point and therefore provide little information about rates of change in quality of life or how pre-ICU quality of life affects quality of life after discharge. Addressing these limitations, Cuthbertson and coworkers [41] prospectively followed 300 consecutive patients admitted to their ICU. They measured quality of life using two different tools at 3, 6, and 12 months after ICU discharge. At 3 months, quality of life was substantially reduced compared to the subjects’ premorbid states. During the ensuing year, quality of life improved and approached the pre-ICU level. Unfortunately, at 1 year, the quality of life of survivors still remained lower than that reported for a general population. Among 109 persons with ARDS, Herridge et al. [32] reported similar patterns in the recovery of quality of life. During 12 months, scores on the SF-36 for physical functioning doubled and those for social functioning rose by 75%.

Several general themes appear in the quality-of-life literature relating to ICU care. First, quality of life is substantially impaired in ICU survivors, but this improves with time after ICU discharge. Second, despite changes in quality of life, this may not return to preadmission levels and the time course of recovery may be slow. Third, it is unclear what factors contribute to the quality of life of ICU survivors and how interventions in the ICU can affect subsequent quality of life.

Hence, many issues remain unresolved in this area of critical care outcomes research. Plaguing efforts to better comprehend this important patient-centered measure are multiple methodologic issues. As one systematic review of quality-of-life studies concluded: “There is no agreement as to the optimal instrument and (that) differences between studies preclude meaningful comparisons or pooling of results” [41]. These concerns explain why there has been a paucity of work in this area and why one group of investigators observed that fewer than 2% of all articles dealing with general critical care published from 1992 to 1995 dealt with this topic [37]. Despite all these concerns, an expert panel on surviving sepsis endorsed the SF-36 as best suited for outcomes research for sepsis patients who received critical care [4].

More recent work with SF-36 among ICU survivors provides some striking observations about survivors relative to population controls. Orweilus et al. examined quality of life among nearly 800 ICU survivors of different ICUs. Compared to nearly 7,000 controls matched for age, gender, and comorbidities, the authors found no significant difference in
quality of life between the groups. On the one hand, this is encouraging news. Alternatively, given the prevalence of PTSD and post-sepsis syndrome, the conclusion that ICU survivors pay no quality-of-life penalty lacks face validity for some. Hence, the issue may be that the SF-36 fails to capture important aspects of HRQL that are unique to survivors of critical illness [42].

In an effort to address this and to simultaneously deal with issues related to quality of life while hospitalized in the ICU, some researches have attempted to design and validate tools for use in the ICU. These tools are specifically targeted for application during critical illness and may even be completed for mechanically ventilated patients. As an example, Pandian and colleagues [43] created such a tool and found that it correlated well with other accepted quality-of-life assessment measures.
A final aspect of critical care outcomes deals with economic and financial issues. The ICU remains a major focus for concerns relating to cost. Part of this arises from the fact that many expensive technologies are applied in the ICU. Simultaneously, ICU bed days are disproportionately expensive compared with costs related to general ward bed days. Adding to increased costs is a growing demand for ICU care. With the aging of the population, the need for critical care resources will escalate. For example, during the next several decades, the incidence of severe sepsis and septic shock has been projected to rise by 30% [44].

Relative to the entire U.S. economy, it was estimated that, approximately two decades ago, ICU costs accounted for nearly 1% of the nation’s gross national product [1]. In a similar analysis, total critical care costs by the year 2000 had nearly tripled from 1984 and now exceeded $55.5 billion annually [3]. As a function of the national economy, however, the proportion of the gross domestic product devoted to the ICU had decreased to 0.56% [3]. Despite this relative fall in the resources consumed by critical care, which essentially reflects the faster growth of the overall U.S. economy compared to ICU expenditures, the ICU now accounts for one in seven dollars spent on hospital care in the United States [3]. On a per-day basis, the most recent analyses indicate that costs for the initial day of MV in the ICU exceed $10,000 and fall to $4,000 per day by ICU day 3 when most subjects are clinically stable [2]. In short, from any perspective, whether societal or local, critical care remains exceedingly expensive.

Although the amounts cited above describe estimated costs generally, it may be that costs vary by admitting diagnosis. This is most clear in the case of ARDS. Bice et al., [45] in a review of costs and outcomes related to ARDS, convincingly document that direct health care costs related to ARDS (to include both fixed and variable costs) are higher than those for other patients needing mechanical ventilation in the ICU.

As a result of this economic pressure, patients, physicians, third-party payers, and policy makers are all demanding improved efficiency and optimization of resource allocation. In the United Kingdom, formal cost analyses have become the purview of regulatory agencies, and recommendations from these authorities influence the adoption of new therapies. In the United States, legislation to require formal economic analyses for the approval of new pharmaceuticals is under consideration. Critical care practitioners, therefore, require an appreciation of economics and finance in order to advocate for their patients and the resources they need to care for the critically ill. The need to appreciate the
financial and economic aspects of care is even more acute now in the United States since CMS has continued to expand its value-based purchasing program.

A Primer on Economic Analysis

Economic analysis represents a means for understanding and appreciating value in order to facilitate the efficient allocation of limited resources in light of competing claims for those resources. In many scenarios, the criteria employed to determine how to spend limited dollars may not be evident or may be filled with assumptions and biases. The essential goal of economic analyses is to make explicit both the means and criteria used for decision-making. Reflecting the growing significance of economic issues, multiple formal position statements now exist describing both the means to conduct and the implications of financial studies for health care [46,47].

There are several basic varieties of economic analyses in health care: cost-minimization, cost-benefit, cost-effectiveness, and cost-utility. Cost-minimization presupposes that the outcome of interest is fixed and competing approaches are equally efficacious. The main issue, therefore, is which alternative costs less. In critical care, though, few interventions achieve similar results, so a more complex means for comparing options is required. When both costs and outcomes differ, it is necessary to assign the distinct options a value in some common schema (such as dollars). After converting potential results of interventions into dollars, one can proceed with cost-benefit analyses. Cost-benefit analyses are rarely used in health care because many end points are not easily converted into dollar values (e.g., the dollar value of a life) and because cost-benefit approaches may inadvertently assign more value to those who have higher earning potential. Cost-effectiveness acknowledges the limitations of cost-benefit and thus leaves the outcome (or denominator) in clinical terms such that one is now comparing costs per common measure of effectiveness. Often-used examples of this for critical care explore costs per year of life saved or per ICU days avoided. Cost-utility analysis builds on cost-effectiveness analysis by adjusting the clinical outcome for the quality that results from the intervention.

The standard denominator for these types of studies is the quality-adjusted life-year (QALY). The QALY concept acknowledges that a year of life spent in a long-term ventilator facility is not viewed by the patient as being of the same quality as a year lived being fully independent.
Although arbitrary, most consider cost-effective interventions that yield a price per QALY saved of between $50,000 and $100,000.

One source of confusion and controversy in economic analyses is estimation of costs. Given the market structure of health care, charges rarely reflect costs. In fact, formal means exist to convert charges to costs based on published cost-to-charge ratios. Analytically, costs can be computed through microcosting, in which the unique costs for each component of care are determined and then summed. Costs can also be estimated based on average bed-day costs. Both approaches have limitations: Microcosting may underestimate the fixed costs associated with care delivery and a bed-day approach assumes that costs remain similar despite the intensity of care the patient requires.

Any conversation about cost, though, has an underlying central question: Cost to whom? This issue of perspective is key in all economic analyses. Some intervention may appear cost-effective to an institution because it shifts costs to a third-party payer. For the payer, though, the intervention will be seen as less than optimal. To address this fact, formal recommendations for the conduct of cost-effectiveness analyses encourage adoption of a societal perspective [46,47]. Utilization of a common societal perspective can also facilitate comparisons across alternatives. However, in critical care, a societal perspective poses specific challenges. As one review notes: “The societal perspective forces consideration of outcomes and costs not usually considered in critical care studies and a time horizon longer than most critical care studies” [47].

Uncertainty represents a final aspect of cost-effectiveness and outcomes that merits mention. All estimates for any study’s inputs are bracketed by assumptions and uncertainty. The issue then becomes how one’s conclusions are affected by this inherent uncertainty. If the costs of an ICU day are half what one assumes, does it alter the outcome of an analysis? Determining the impact of this uncertainty is best done through sensitivity analyses. Sensitivity analysis is a tool for varying a model’s inputs across a range of assumptions and seeing if and how the results vary in response to this. If introducing such variability fails to affect the conclusions, one can be more confident as to the strength of the outcomes.

**Disease-Specific Costs**

Multiple studies in the last several years have attempted to gauge the costs of various diseases commonly encountered in the ICU. These reports help provide estimates of disease-state costs, which can be then used for cost-effectiveness analyses of preventive interventions or be relied on for budget planning.
With respect to nosocomial infection, Warren et al. [48] calculated the attributable cost of a catheter-related blood stream infection (CRBSI) to be nearly $12,000 per event. Their study prospectively followed a cohort of critically ill subjects and compared those developing CRBSIs to those not suffering this complication. In addition, they controlled for multiple potential confounders such as severity of illness, use of MV, and need for dialysis. Blot et al. [49], in a retrospective case-controlled study in Europe, reached similar conclusions. They reported that a CRBSI significantly prolonged the duration of MV and ICU length of stay and resulted in net excess costs totaling €14,000 [49]. Reflecting these high costs, multiple preventive strategies have been shown to be cost-effective. In an analysis of a multifaceted educational intervention emphasizing the pathogenesis, implications, and prevention of CRBSI, researchers from Washington University demonstrated that their efforts saved approximately $500,000 during the course of a year [50]. Likewise, use of chlorhexidine rather than povidone, adherence to the need for full barrier drapes, and adoption of antibiotic-impregnated catheters have been shown to yield net savings despite their initially high acquisition costs.

Ventilator-associated pneumonia also represents a common and costly ICU-acquired infection. Rello and coworkers [51] observed that the costs of this disease exceeded $40,000 per case. This analysis, though, was limited because it was a retrospective assessment of a large administrative database such that the definition of pneumonia employed might have led to selection bias. Alternatively, Warren et al. [52], in a prospective study of a community ICU, suggested that the costs of ventilator-associated pneumonia were similar to those reported by Rello et al. Hence, two distinct studies using different approaches reached similar conclusions.

For non-ICU acquired processes, community-acquired pneumonia (CAP) represents a major driver of national health care expenditures by the U.S. government. Describing outcomes in a cohort of patients with severe CAP, Angus et al. [53] suggested that persons with CAP needing ICU care generated total hospital costs in excess of $21,000. Strikingly, this amount was more than three times greater than the costs for inpatient CAP not needing ICU admission. From a societal perspective, Kaplan et al. [54] reviewed data from Medicare and calculated that national ICU costs for CAP surpassed $2.1 billion. The financial implications of sepsis are also staggering. Multiple reports document hospital costs per case at approximately $30,000 to $40,000 [55, 56]. An analysis by Shorr and coworkers [57] suggested that the costs per case for severe sepsis exceeded $30,000 per case with survivorship being associated with lower per-patient costs. Costs in Europe were seen to be somewhat lower than those noted in the United States. For example,
Adrie et al. [58] prospectively recorded costs for sepsis in six French ICUs. The mean cost of severe sepsis equaled €22,800. They further described that sepsis costs varied based on whether the infection was community-acquired or evolved while the subject was hospitalized. In attempting to determine cost drivers in sepsis, Burchardi and Schneider [59] reviewed multiple costing reports and concluded that direct costs account for only 20% to 30% of overall costs in sepsis.

### Cost-Effectiveness Studies in Critical Care

Coincident with the growing interest in cost-containment in critical care has been a rise in the number of formal cost-effectiveness analyses published in this field. Examples of such analyses have explored multiple resource-intense processes such as the use of MV in ARDS, and reliance on renal replacement therapies (RRT) for acute renal failure in the ICU. In ARDS, Hamel et al. [60] used information from the Study to Understand the Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) to investigate the value of MV. They estimated that ventilatory support was a cost-effective strategy overall, but that the cost-effectiveness ratio varied from $29,000 per QALY saved to $110,000 per QALY based on the subject’s initial risk of death. Their analysis was insensitive to patient age as the cost-effectiveness ratio in subjects younger than 65 years was $32,000 versus $46,000 per QALY in those older than 75 years. One strength of this analysis was its close follow-up of patients, and thus the ability to more precisely account for postdischarge health care utilization. Cooke and coworkers conducted a similar analysis focusing on the cost-effectiveness of low tidal volumes in ARDS. Not surprisingly, given the few costs related to implementing a low-tidal-volume approach along with the substantial mortality benefit related to this, low-tidal-volume use is a dominant economic strategy [61].

Also using similar techniques, Korkeila et al. [62] investigated RRT. They tracked patients needing RRT and calculated that the costs per 6-month survivor were $80,000. In a comparable study to the one by Hamel et al., [63] the SUPPORT investigators reported that the cost per QALY saved by initiating dialysis and continuing aggressive care was $128,000. Again, underlying prognosis, not surprisingly, affected the cost-effectiveness ratio. In the best prognosis group, cost per QALY approached $68,000. In the worse prognosis group, it measured $274,000 per QALY saved. The authors concluded that, except in those
with exceedingly good prognoses, this approach was not cost-effective. Readers should note that these cost estimates are from nearly a decade ago, and if updated to reflect health care inflation would only reinforce the impression that acute RRT has substantial financial implications for society.

Although not a definitive review of the many cost-effectiveness analyses performed in critical care outcomes research, these three examples illustrate that this approach can be used successfully to inform both professional and policy dialogue. They also help to demonstrate the value of ICU care despite its seemingly expensive implications for third-party payers and national governments. Uniformly, these reports illustrate that it is possible to measure proxies for cost rather easily and hence should become routine in the conduct of clinical research. Cost researchers, alternatively, need to be cautious as the time period they choose to study (e.g., short term, intermediate term, and long term) can affect their results and conclusions. Short-term costs may be saved with a novel intervention. Over the longer term, though, what might have appeared attractive economically could result in major costs to society.
CONCLUSIONS

Outcomes research remains an emerging field in critical care. As appreciation of patient-centered issues expands along with improved understanding of the diseases treated in the ICU, the need for more extensive and refined outcomes research will grow. Outcomes research, fortunately, encompasses a wide area of interest, and patient-centered outcomes can now be better folded into end points of clinical trials. Although methodologic issues continue to exist and further refinement in analytical techniques is required, the practicing intensivist benefits from an understanding of the issues central to outcomes research.

ENDOCRINE PROBLEMS IN THE INTENSIVE CARE UNIT

NEIL ARONIN • DAVID M. HARLAN
INTRODUCTION

Hyperglycemia is a common problem that complicates the delivery of intensive care. By 2014 estimates, 29.1 million people, or 9.3% of the U.S. population, have diabetes [1]. On the basis of 2000 to 2011 National Health Interview Survey data, the lifetime risk of diabetes for a 20-year-old in the United States is estimated at approximately 40% [2]. In addition, the growing worldwide prevalence of obesity is increasing the prevalence of diabetes for many nations [3]. The global prevalence of diabetes among adults is predicted to be 7.7%, or 439 million adults, by 2030 [4]. Epidemiology alone would make diabetes a common problem in the intensive care unit (ICU), but poorly controlled diabetes also predisposes to cardiovascular [5,6], renal [7–9], and infectious [10–16] complications that often require intensive surgical and medical care. In addition, hyperglycemia frequently occurs among severely ill ICU patients who have no prior history of diabetes [17,18].

Whatever the primary problem, hyperglycemia amplifies the challenges of intensive care. Often, preexisting diabetes itself is the primary problem, as in ketoacidosis and hyperosmolar coma. These conditions are discussed in Chapter 137.
ETIOLOGY AND PATHOPHYSIOLOGY

Metabolic Homeostasis

Individuals with normal glucose tolerance maintain their blood glucose concentration between 60 and 120 mg per dL. Maintenance of glucose within this narrow range is controlled by the degree of tissue insulinization (Fig. 136.1) [19]. This is a function of the amount of insulin available and the responsiveness of target tissues. After eating, blood glucose concentration rises but remains within the normal range as a result of increased insulin secretion. Insulin first promotes the transport of glucose into cells and the repletion of glycogen and protein stores. It then mediates the storage of excess glucose as triglycerides. When absorption of nutrients is complete, the concentrations of all metabolites and hormones return to basal levels.

![Figure 136.1: Metabolic effects of insulin in normal and diabetic states. Upper: entries illustrate the anabolic, storage-promoting effects of insulin that occur with eating. Middle: entries illustrate the controlled catabolic effects that occur during fasting. Bottom: entries illustrate the uncontrolled catabolism that ensues from absolute deficiency of insulin in type 1 diabetes.](p. 1259)
In the fasting state, two mechanisms keep blood glucose concentration in the normal range, glycogenolysis and gluconeogenesis. Initially, hepatic glycogen is mobilized. If fasting persists longer than 12 to 18 hours, peripheral tissues begin to use free fatty acids for fuel, thereby sparing glucose. A low level of circulating insulin is permissive to the lipolytic release of these fatty acids. At the same time, gluconeogenesis supplies glucose for obligate glycolytic tissues, most notably the central nervous system.

When starvation continues for more than 72 hours, the brain begins to use ketone bodies as an alternative fuel, further sparing glucose utilization [19]. At this stage, a progressive decrease in hepatic gluconeogenesis occurs as a consequence of decreased amino acid release in the periphery. As starvation continues, lactate, pyruvate, and glycerol become the main gluconeogenic precursors in place of amino acids. At all times, a low level of circulating insulin regulates the rate of lipolysis, glucose transport, and gluconeogenesis. Healthy humans always have detectable and appropriate levels of insulin (i.e., adequate insulinization).

**Metabolic Stress**

Major surgery and critical illness are physiologically stressful events that provoke complex metabolic responses. Tissue hypoxia and hypoxemia adversely affect normal oxidative phosphorylation, and counterregulatory hormones are secreted. These hormones include epinephrine, norepinephrine, cortisol, growth hormone, glucagon, and various cytokines (e.g., tumor necrosis factor-α). They raise blood glucose concentration, mobilize alternative fuels, and increase peripheral resistance to the effects of insulin. For the ICU patient, their effects may be further amplified by the concurrent administration of exogenous vasopressors, glucocorticoids, and other drugs that can affect intermediary metabolism.

**Stress and the Diabetic State**

Stress-induced changes in metabolism normally lead to increased insulin release. This in turn enhances peripheral glucose utilization and inhibits alternative fuel mobilization. In this way, the body resists stress without losing control of the biochemical machinery. Among patients with decreased insulin reserves (i.e., diabetes mellitus), failure of this feedback loop produces hyperglycemia and related metabolic complications. To preclude these complications, careful management of insulin, fluid, and electrolytes is necessary.

**Classification of Diabetes**
Diabetes is not one disease but rather a family of syndromes that have in common hyperglycemia resulting from inadequate insulinization. These syndromes vary with respect to genetics, pathophysiology, and appropriate treatment modalities. Table 136.1 outlines the American Diabetes Association’s classification system [20].

### TABLE 136.1 Classification of Diabetic Syndromes [20]

| Type 1 diabetes (β-cell destruction) autoimmune (Type 1A) and idiopathic (Type 1B) |
| Type 2 diabetes (insulin resistance with variable insulin secretory defect) |
| Other specific types |
| Genetic defects of β-cell function (e.g., MODY, mitochondrial DNA) |
| Genetic defects in insulin action (e.g., lipoatrophic diabetes) |
| Diseases of the exocrine pancreas (see Table 136.2) |
| Endocrinopathies (see Table 136.2) |
| Drug or chemical induced (see Table 136.2) |
| Infections (e.g., congenital rubella) |
| Uncommon forms of immune-mediated diabetes (e.g., stiff-man syndrome) |
| Other genetic syndromes associated with diabetes |
| Gestational diabetes mellitus |

MODY, maturity-onset diabetes of the young.

### Type 1 Diabetes

In type 1 diabetes, the insulin-producing β cells of the pancreatic islets are destroyed, resulting in near total deficiency of insulin [19,21]. Hyperglycemia develops rapidly, most commonly during childhood and adolescence. Most cases of type 1 diabetes are autoimmune in origin [21]. About 5% of persons with diabetes have this form of the disorder [1].

Patients with type 1 diabetes require exogenous insulin for survival (Fig.136.1). The insulin can be given either as a continuous insulin infusion or as conventional subcutaneous injections. The key ICU issue is continuity of treatment. Inappropriate discontinuation of insulin treatment, even for relatively brief intervals, can lead to serious metabolic complications.

Patients with type 1 diabetes who are not given insulin can neither store nor use glucose, and unregulated gluconeogenesis and lipolysis
occur (Fig. 136.1). In this hypercatabolic state, accelerating amino acid and fat mobilization produce hyperglycemia, hyperlipidemia, and ketosis. The excess glucose produced by uncontrolled gluconeogenesis remains in the circulation, because there is no insulin to stimulate glucose transport into cells. The osmotic diuresis of glucose and the buffering of ketoacids produce secondary fluid and electrolyte shifts. Ultimately, diabetic ketoacidosis occurs. This disorder is discussed in Chapter 137.

**Type 2 Diabetes**

Type 2 diabetes is characterized by relative, rather than absolute, deficiency of insulin. It involves defects in both insulin action and insulin secretion. Impaired response to insulin of peripheral tissues is often the dominant feature [22–25]. It develops insidiously, most commonly among obese individuals more than 40 years old, although it is now increasingly diagnosed at younger ages. It may go undetected for years, only to be discovered serendipitously or during the stress of surgery or other illness.

Many patients with type 2 diabetes can be treated with diet, exercise, and oral hypoglycemic agents. Some patients, especially those who are not obese, need insulin to control their hyperglycemia. This is done to prevent symptoms (e.g., polyuria) and long-term complications. Even when type 2 diabetes is untreated, there is usually enough insulin present to control lipid mobilization and prevent ketoacidosis when the patient is otherwise well. They can, however, develop diabetic ketoacidosis (DKA) in the presence of sufficient intercurrent stress.

In the ICU, patients with type 2 diabetes whose diabetes is uncontrolled should be treated with insulin. Keys to management include attention to both blood glucose concentration and acid–base balance. Infection, metabolic stress, and many medications commonly used for ICU patients can exacerbate type 2 diabetes and lead to ketoacidosis [26], hyperosmolar coma, or lactic acidosis. These disorders are discussed in Chapter 137.

**Other Types of Diabetes**

Additional forms of diabetes involve specific genetic defects or are secondary to intercurrent diseases, infections, medications, or a combination of these [27]. The broad categories into which these other specific types of diabetes fall are given in Table 136.1. A partial listing of the other types of diabetes and precipitants of secondary diabetes is given
in Table 136.2.

</table>
ICU patients with any form of uncontrolled hyperglycemia require insulin to control hyperglycemia and prevent short-term metabolic complications. Patients who have undergone total pancreatectomy have absolute insulin deficiency, are ketosis prone, and are insulin dependent. Patients with other diseases of the exocrine pancreas (e.g., pancreatitis) can develop variable degrees of insulin deficiency and, while in the ICU, should be considered at risk for ketoacidosis. Gestational diabetes of an ICU patient should also be treated with insulin.
DIAGNOSIS OF HYPERGLYCEMIA FOR THE INTENSIVE CARE UNIT PATIENT

Diagnostic Criteria

All acutely ill patients should have their blood glucose level measured at entry into the ICU and at regular intervals throughout their stay. In the outpatient setting, diabetes is diagnosed by a fasting blood glucose level over 126 mg per dL, or a glucose level greater than or equal to 200 mg per dL measured 2 hours after a 75-g oral glucose tolerance test. A formal diagnosis of new onset diabetes should be made tentatively during the stress of an ICU admission as hyperglycemia may subsequently resolve. Hyperglycemic ICU patients with no prior history of diabetes should be evaluated for persistence of impaired glucose tolerance after recovery.

The majority of seriously ill patients with hyperglycemia do not have a preexisting diagnosis of diabetes. In one study of 1,200 subjects treated in a medical ICU, 70% of individuals at some time experienced a plasma glucose concentration of more than 215 mg per dL, and only about 17% of these patients had a prior history of diabetes [28].

Assessment of Severity

Whenever the glucose concentration of any patient is greater than about 250 mg per dL, actual or impending ketoacidosis and hyperosmolality must be considered. Ketoacidosis can be diagnosed on the basis of history, physical findings, and the presence of an anion-gap acidosis and ketonemia. Osmolality can be measured by the laboratory or calculated from the serum concentrations of glucose, blood urea nitrogen, sodium, and potassium (Table 137.1 of the comas Chapter 137). Hyperosmolar states in the setting of diabetes are usually associated with severe dehydration, obtundation, and extreme hyperglycemia. Diabetic ketoacidosis and hyperosmolar coma require urgent treatment (see Chapter 137). In this chapter, we describe the goals, methods, and pitfalls of treating intercurrent diabetes mellitus in the ICU when neither ketoacidosis nor hyperosmolar coma is the primary disease process.
TREATMENT OF CRITICALLY ILL PATIENTS WITH PREEXISTING DIABETES

Initial Evaluation

Physicians caring for patients with diabetes in an ICU should attempt to determine the type of diabetes, its duration, the presence of diabetic complications, and the degree of previous glycemic control. Patients with type 1 diabetes require insulin treatment at all times; those with type 2 diabetes may or may not require insulin. Patients with diabetes that is secondary to some other disorder (Table 136.2) require diagnosis and treatment of the precipitating factors.

Long-standing diabetes is associated with complications that tend to be more severe for patients with glycemia that is poorly controlled [29,30]. These sequelae of diabetes complicate the management of critical illnesses. Diabetes is a leading cause of cardiovascular and peripheral vascular disease. Assessments of both cardiac function and peripheral circulation are advisable for all patients with diabetes. Diabetic neuropathy can affect the autonomic nervous system, with implications for managing blood pressure, heart rate, and voiding. Autonomic neuropathy should be suspected in patients with an abnormal pupillary response to light or absence of heart rate response (R-R interval change in the electrocardiogram) during a Valsalva maneuver. Assessment of kidney function should include a urinalysis for protein; albuminuria precedes abnormalities of blood urea nitrogen and creatinine levels. Diabetic eye disease is not a contraindication to anticoagulation, but its severity should be documented before instituting therapy.

A history of poor glycemic control should alert the clinician to other potential problems. Poorly controlled diabetes is associated with poor nutrition. This has important implications for resistance to infections and for wound healing; nutritional assessment and vitamin repletion may be helpful. Thiamine, in particular, is a critical cofactor in carbohydrate metabolism, and patients with uncontrolled diabetes may be thiamine deficient. Occult infections to which individuals with diabetes are particularly susceptible include osteomyelitis, cellulitis, tuberculosis, cholecystitis, gingivitis, sinusitis, cystitis, and pyelonephritis [11,12,31,32]. Patients with type 2 diabetes frequently have hypertriglyceridemia and may develop pancreatitis because of high levels of triglycerides [33].

Hospital-grade bedside blood glucose monitoring systems for point-of-care glucose determinations are accurate [34,35], but can be influenced
by hematocrit, creatinine concentration, plasma protein concentration, and PO₂, all of which can be abnormal among ICU patients [36–38]. Extremely elevated blood glucose concentrations may be outside the range accurately measured by the bedside monitor and should be verified with a serum sample sent to the laboratory [39]. In general, however, therapy should not be delayed by waiting for confirmatory results of laboratory glucose concentration in the proper clinical setting.

Promising new technology for continuous glucose monitoring (CGM) has the potential to improve detection and prevention of hypoglycemia in ICU [40]. CGM devices that measure subcutaneous glucose readings may be less accurate in patients with impaired microperfusion such as occurs during extracorporeal ventricular assist therapy [41]. Invasive indwelling intravascular sensors that measure blood glucose directly are also under development and have the potential for increased accuracy for critically ill patients [42]. The ultimate goal is to couple CGM devices to intravenous insulin infusions as a closed-loop artificial pancreas system [43].

**Why Control Hyperglycemia During Critical Illness?**

**Hyperglycemia Among the Critically Ill Predicts Adverse Outcomes**

It is intuitively plausible to assume that glucose concentration should always be in the normal range, and studies show that hyperglycemia among critically ill patients is associated with adverse outcomes. Even minimal hyperglycemia, plasma glucose concentration >110 mg per dL, has been shown to predict increased in-hospital mortality and the risk of congestive heart failure among patients with acute myocardial infarction [44]. Hyperglycemic patients also have an increased risk of wound infection as well as overall mortality following cardiac surgery [45,46]. Hyperglycemia is also associated with poor outcomes among patients with stroke [47]. Patients in whom diabetes is diagnosed for the first time during an ICU admission reportedly have an 18-fold increase in their risk of in-hospital mortality [48].

**How Does Hyperglycemia Adversely Affect Outcomes?**

Hyperglycemia predisposes to disturbances in sodium, potassium, and phosphate concentrations. Because uncontrolled hyperglycemia also provokes an osmotic diuresis, symptomatic hyponatremia can result. Hypokalemia predisposes to arrhythmia, and hypophosphatemia may interfere with platelet function and white cell motility. Control of
glycemia prevents these problems and the need for compensatory correction. The susceptibility of patients with diabetes to infections is well recognized [11,12,31]. Uncontrolled glycemia appears to impair innate immunity (cytokine, pathogen recognition pathways, and phagocytic capacity), granulocyte function (chemotaxis, phagocytosis, and killing), and, possibly, lymphocyte function and adaptive immune function, including antibody formation [49–52]. Some microorganisms express more virulence factors in a high-glucose environment [49]. Endothelial functions may also be impaired by hyperglycemia [53]. In general, better regulation of blood glucose leads to improvement of these parameters.

What is the Evidence that Control of Blood Glucose Concentration Alters Clinical Outcomes for Intensive Care Unit Patients?

Recognizing that hyperglycemia is a risk factor for adverse outcomes is not the same as saying that tight control of hyperglycemia for critically ill patients, with the attendant risk of hypoglycemia, is beneficial. Hyperglycemia, hypoglycemia, and increased glycemic variability are all independently associated with mortality of critically ill patients [54].

In 2001, a widely discussed study of surgical ICU patients by Van den Berghe et al. [55] reported that intensive insulin therapy with a “near-normal” target plasma glucose concentration <110 mg per dL reduced in-hospital mortality by 34%, septicemia by 46%, acute renal failure by 41%, and critical-illness polineuropathy by 44%. This study, together with the results of other single-institution reports and retrospective studies [46,56,57], generated widespread acceptance of the concept that intensive glycemic control is important for critically ill patients. This then led to implementation of intensive glycemic control protocols in a majority of academic ICU programs [58].

A subsequent report from the Van den Berghe group [28] as well as two large multicenter randomized controlled trials of blood glucose management of heterogeneous ICU populations failed to show benefits for near-normal diabetes control in the ICU. The GLUControl trial randomized 3,000 medical and surgical ICU patients in several centers in Europe to two regimens of insulin therapy targeted to achieve a plasma glucose concentration of either 80 to 110 mg per dL or 140 to 180 mg per dL [59]. The trial was stopped early because of an increased frequency of
hypoglycemia together with lack of clinical benefit in the intensive insulin therapy cohort. The NICE-SUGAR (Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation) trial randomized 5,000 medical and surgical ICU patients at multiple centers in Australia, New Zealand, and Canada to intensive (81 to 108 mg per dL) or conventional (≤180 mg per dL) management [60]. The investigators reported that intensive glucose control increased mortality and the rate of hypoglycemia compared with the conventional target cohort.

A number of trials have now highlighted the importance of avoiding hypoglycemia of the critically ill patient [61]. Among critically ill patients, an association exists between even mild or moderate hypoglycemia and mortality [62,63] (See also Chapter 138). Preexisting diabetes increases the risk of mortality from hypoglycemia; the higher the glucose level before admission to the ICU, the higher the mortality risk when patients experienced hypoglycemia [64]. It has been suggested that patients with diabetes may benefit from higher glucose target ranges than will those without diabetes [54,64]. The preponderance of available evidence suggests that intensive management of hyperglycemia to within the normal range for critically ill adults is not beneficial, although the precise ideal target is still controversial [65,66].

Recommended Glycemic Targets

The American Diabetes Association (ADA) recommends a glycemic target of 140 to 180 mg per dL in the ICU setting, noting that greater benefit may be realized at the lower end of this range [67]. Table 136.3 summarizes our recommendations. Glucose concentrations of less than 80 mg per dL should be stringently avoided because they pose the hazard of hypoglycemia and might contribute to mortality [55,62,63]. An intensive insulin treatment program to achieve the American Association of Clinical Endocrinologists (AACE)/ADA targets requires a strong institutional commitment. It is a team effort requiring participation of physicians, nursing, and pharmacy staff.

At our institutions, we recommend that all intensive care unit patients with blood glucose concentrations >140 mg/dL be treated with a continuous intravenous infusion of regular insulin with a target as close as possible to 140 [67]. A less stringent target range may be preferred during the perioperative period and whenever staffing or training constraints prevent the implementation of more intensive therapy. Patients with type 1 diabetes must be treated with insulin at all times.

Treatment of Hyperglycemia for the Critically Ill

The majority of ICU patients will require treatment for hyperglycemia, and we recommend that they be treated with a continuous intravenous infusion of regular insulin. This is irrespective of prior history of diabetes or previous treatment modalities. Patients known to have type 1 diabetes are absolutely insulin dependent, and they must be treated with exogenous insulin at all times. Oral hypoglycemic agents should not be used in the ICU for many reasons. Their absorption, metabolism, and excretion cannot be adequately predicted for the individual critically ill patient. Sulfonylureas can cause severe hypoglycemia [68] (See Chapter 138). Metformin should be discontinued because it can cause lactic acidosis in the setting of renal failure [69]. SGLT-2 inhibitors can lead to dehydration and euglycemic DKA [70,71].

Our recommendations for the management of patients with ketoacidosis or hyperosmolar syndrome are given elsewhere (see Chapter 137). For patients whose primary ICU diagnosis is not diabetic ketoacidosis or hyperosmolar hyperglycemic syndrome, we recommend the treatment program advocated by the AACE and ADA [67].

Insulin Therapy

Although optimal glycemic targets are now agreed to, insulin infusion algorithms to achieve those targets need to be individualized by the responsible multidisciplinary teams. Every protocol will require development of guidelines for adjustment of the insulin infusion rate in response to both the absolute value and the rate of change in the glucose concentration. Glucose concentration should be checked hourly until it is consistently in the target range of 140 to 180 mg per dL, and every 2 to 4 hours thereafter. During the initial period, adjustments to the insulin infusion rate will depend on the patient’s sensitivity to insulin (see below) and the observed response to therapy, which cannot be exactly predicted. Concurrent glucose infusions or parenteral or enteral feeding will also affect the dose required. Tight glycemic control has been associated with a high incidence of hypoglycemia and an increased risk of death in patients not receiving parenteral nutrition [72]. A list of currently available insulin preparations is given in Table 138.2 in Chapter 138.
Diluted insulin solutions prepared from continuous insulin infusions have a limited storage life because insulin adheres to the plastic infusion bag. There is no advantage to the use of rapid-acting semisynthetic insulin for this purpose, but it can be used when regular insulin is unavailable. It should be stressed that it is entirely appropriate to infuse insulin at low rates (e.g., 0.5 U per hour). A low rate of insulin infusion is often all that is needed to prevent ketoacidosis among patients with type 1 diabetes.

Adjustment of the Insulin Infusion Rate

The amount of insulin required by a given ICU patient will depend in large part on the degree of insulin resistance induced by the primary illness, the agents used in its treatment, and the patient’s body mass index. It will also depend on the type and amount of nutritional support being given. An escalating insulin infusion requirement is a sensitive indicator of increasing insulin resistance and requires careful reevaluation of the patient’s overall metabolic status. Stressors that increase insulin resistance include sepsis, occult infections, heart disease, tissue ischemia, hypoxemia, and various medications. The most common offending medications are glucocorticoids and vasopressors.

In otherwise stable patients, instituting or increasing enteral or parenteral nutrition typically increases insulin requirements. Insulin-mediated glucose disposal is impaired among stressed patients with hyperglycemia, and even extremely high insulin infusion rates cannot prevent hyperglycemia due to unmanageable carbohydrate loads. To control hyperglycemia among the critically ill, a choice must sometimes be made between increasing insulin infusion rates and reducing carbohydrate feeding. We recommend that insulin infusion rates not be increased beyond 20 units per hour (480 units per day) without first decreasing any exogenous carbohydrate loads, especially for patients who are obese. This suggestion is based on the fact that maximal insulin effects are achieved when only some of the available insulin receptors are occupied [73,74]. High concentrations of insulin, such as those achieved during continuous intravenous infusions at high rates, desensitize target tissues at both the receptor and postreceptor levels, paradoxically enhancing insulin resistance [75].

Factors that increase insulin sensitivity among critically ill patients include improvement of intercurrent illnesses, changes in medications, and reductions of enteral or parenteral feeding. Occasionally, hepatic
failure, renal failure, or adrenal insufficiency leads to decreased insulin requirements.

When plasma glucose concentration is lower than 140 mg per dL, a common response is to discontinue insulin completely. For patients with type 1 diabetes, this is *always inappropriate* because it can precipitate hyperglycemia and ketosis within hours. The proper response is to reduce the insulin infusion rate to 1 or even 0.5 units per hour and, if necessary, to give glucose in the form of 5% or 10% dextrose in water. We recommend the same strategy for most other hyperglycemic ICU patients as well. Unless their primary disease state has improved dramatically, they frequently experience recurrent hyperglycemia. Critically ill patients with hyperglycemia should receive continuous intravenous insulin until they demonstrate clear improvement of overall clinical status and stability of glycemic control that extends over several blood glucose determinations.

**Transition to Other Forms of Therapy**

When the condition of a critically ill patient with hyperglycemia has improved to such an extent that continuous insulin infusion is no longer needed, subsequent therapy will depend on the cause of the hyperglycemia. Patients with “secondary diabetes” (e.g., catecholamine- or steroid-induced) may need no further treatment for glucose control after the offending drug is stopped. In contrast, all patients with type 1 and most with type 2 diabetes will continue to require insulin. This should include intermediate- or long-acting insulin, e.g., neutral protamine Hagedorn (NPH), glargine, or detemir (See Table 138.2 in Chapter 138 for details). We recommend against the use of insulin degludec for inpatients since its duration of action of up to 42 hours limits options for daily adjustment.

It is not uncommon for glycemic control to deteriorate during the transition from intravenous insulin therapy to subcutaneous insulin therapy. It is essential that the intravenous infusion of regular insulin be continued for 2 to 3 hours after the first subcutaneous injection of insulin is given. The initial dose of subcutaneous insulin should be estimated from a review of the preceding intravenous insulin requirements. Presumably at the time the patient is ready to transition to subcutaneous therapy, he or she will have had reasonably stable insulin requirements. We recommend basing this dose on the average hourly insulin requirement during the 6 hours prior to discontinuation of the insulin drip using the following procedure:

**Calculating the Starting Intermediate (NPH) or Long-**
Acting (Glargine or Detemir) Insulin Dose

1. The average hourly insulin drip rate for the last 6 hours is ___ units per hour.
2. Multiply by 24 to give a daily usage rate: ___ units per day.
3. Multiply by 70% to 85% to estimate the first day’s total insulin dose: ___ units.
4. All can be administered in divided doses twice daily; glargine and detemir can be given once daily. Dose adjustment may be necessary after first dose given. Review daily thereafter.

When patients are able to eat, a rapid-acting insulin (e.g., lispro, aspart, or glulisine) should be given before each meal. Some stable patients with type 2 diabetes can be managed with oral hypoglycemic agents (Chapter 138, Table 138.3) or diet alone, but that therapeutic decision is best made after discharge from the ICU on a regimen of subcutaneous insulin.
Critically ill patients frequently require invasive procedures, surgery, and intensive postoperative care. In such situations, the treatment of intercurrent diabetes is obviously of importance. The possibility of diabetes must be considered during all surgical emergencies, and both glucose and electrolytes must be measured immediately. A critically ill patient with diabetes, even when previously undiagnosed, can rapidly develop metabolic derangements.

It is generally accepted that good perioperative control of glucose is desirable, but the target levels of glucose and the ideal method of insulin delivery during surgery need to be individualized [76]. Perioperative control of blood pressure and vascular responses may be as important as glucose control for prevention of adverse perioperative events.

Abdominal pain accompanied by guarding and rebound tenderness is a common symptom of diabetic ketoacidosis. The diagnosis of diabetic ketoacidosis has on occasion been made at laparotomy, and this disorder must be excluded in every patient being evaluated for an abdominal surgery. The patient with trauma being prepared for surgery should also be evaluated for diabetes, regardless of mental status. The stress of major trauma and shock is less likely to be survived if ketoacidosis or hyperosmolality is present or allowed to develop. Severe trauma causes the release of counterregulatory hormones, cytokines, and other unidentified factors that can rapidly induce a state of severe insulin resistance.

Transfers from the Intensive Care Unit to the Operating Room

The ICU patient with diabetes who requires surgery should be sent to the operating room or procedure suite with infusions of both insulin and 5% dextrose in half-normal saline.

Management During Emergency Surgery

Treatment of hyperglycemia of diabetic patients being prepared for urgent major surgery is also best achieved with an intravenous insulin infusion. Frequent monitoring of blood glucose levels is essential. Proper fluid and electrolyte balance must accompany the proper degree of insulinization; the amount and the type of fluid administered must be
assessed on an individual basis.

In general, premedication of patients with diabetes should be kept to a minimum. With respect to the type and the route of anesthesia, the regional and local are preferred if possible. Inhalant and parenteral anesthetics affect carbohydrate metabolism either directly through impairment of insulin secretion or indirectly through interference with the peripheral action of insulin on glucose utilization [76–78]. Volatile anesthetics including halothane and isoflurane inhibit insulin release, and nitrous oxide, promote sympathetic stimulation and catecholamine release. Barbiturates share some of these effects and also block the removal of glucose and perhaps free fatty acids from the circulation. Some anesthetic agents, including halothane, have also been associated with hypoglycemia (see Chapter 138, Table 138.4).

Management After Emergency Procedures

Patients managed with an insulin infusion must either be maintained on the infusion or switched to subcutaneous intermediate-acting insulin. Those kept on the infusion must have frequent blood glucose testing. Patients no longer critically ill who are able to resume oral feedings can generally resume their usual insulin regimen. The most important point is that insulin should not be abruptly discontinued, because severe hyperglycemia and ketosis may ensue. Patients who remain critically ill should remain on a continuous intravenous insulin infusion.

Postoperative recovery in the ICU may be accompanied by reduced levels of counterregulatory hormones and cytokines and may require reduced insulin doses. An increase in insulin requirements during the postoperative period may signify increasing insulin resistance and should prompt the search for infection or another complication.

Hyperalimentation and Diabetes

If blood glucose rises above 140 mg per dL for a severely ill patient on hyperalimentation, an insulin infusion should be administered. The hyperalimentation should be continuous. The admixture of insulin with parenteral nutrition formulations, although a common practice, can be problematic. There is too much variability among severely ill patients to rely on a fixed ratio of insulin to carbohydrate. If insulin is added to parenteral nutrition formulations, the dose should be limited to less than 50% of the individual’s total insulin requirement, with the residual
administered by intravenous insulin infusion or subcutaneous injection. This allows rapid adjustment of the insulin dose for changing metabolic needs. If an obese patient receiving hyperalimentation develops severe hyperglycemia and a large insulin requirement, consideration should be given to reducing the amount of carbohydrate administered [79,80]. ICU physicians should be aware that infusions of fructose, sorbitol, and other total parenteral nutrition formulations have occasionally led to lactic acidosis [81].
PITFALLS IN THE CARE OF THE CRITICALLY ILL PATIENT WITH HYPERGLYCEMIA

Sliding Scales

We cannot overstate the need to obtain frequent blood glucose specimens for evaluating glucose control. During critical illness, these should be used to guide adjustments of the rate of insulin infusion. There is no role for intermittent insulin boluses that are given only after hyperglycemia has occurred [82]; the use of “sliding scales” should be actively discouraged [83]. Patients with type 1 diabetes whose insulin is withheld until hyperglycemia occurs can quickly become ketoacidotic.

A patient who has begun taking insulin should continue to receive it daily until the need has unequivocally disappeared. A previously normoglycemic patient who develops hyperglycemia in the course of a severe illness should be treated continuously with insulin until the stress of the illness has been reduced to the point at which an independent assessment of the need for insulin can be made.

Sporadic Insulin Administration

Unfortunately, some patients are treated with regular insulin injections on an intermittent schedule, whenever a very high blood glucose concentration is noticed. This disorganized approach to the management of hyperglycemia leads to erratic glycemic control and potentially serious shifts in fluids and electrolytes. The best way to avoid these problems is to maintain ICU patients with hyperglycemia on a continuous infusion of regular insulin.

Hypoglycemia due to Sensitivity to Short-Acting Insulin

Unusual sensitivity to insulin can be observed in two situations. The first is in some patients presenting with hyperosmolar hyperglycemic syndrome. When treated with short-acting insulin, their glucose concentrations may decline very rapidly. This problem is discussed in
Chapter 138. The second situation occurs in patients with long-standing type 1 diabetes. They sometimes develop extreme sensitivity to the glucose-lowering effects of short-acting insulin. The reason is unclear, but this sensitivity frequently contributes to increased risk of hypoglycemia. This is principally a problem for outpatient management and should rarely complicate insulin infusion therapy. However, among insulin-dependent patients with long-standing diabetes, the initial use of short-acting insulin should be approached with some caution. Hypoglycemia can result from the use of as little as 5 to 10 units given either subcutaneously or intravenously. When short-acting insulin is needed for patients who are suspected to be sensitive, the initial doses should be small (2 to 4 units) and the response monitored by bedside blood glucose determinations. This is particularly important because these patients may have intercurrent hypoglycemia–associated autonomic failure with hypoglycemia unawareness and defective counterregulatory hormone responses [84].

The Diabetic Kidney and Radiographic Contrast Agents

Acute hyperglycemia appears to be an independent risk factor for the development of contrast-induced nephropathy (CIN). The risk of CIN is even greater for the diabetic patient with preexisting renal insufficiency, hypotension, congestive heart failure, or anemia. Mehran et al. [85] have developed a scoring system that can be used to quantify the risk of CIN. Consensus guidelines recommend adequate intravenous volume expansion with isotonic crystalloid (1.0 to 1.5 mL/kg/h) for 3 to 12 hours before the procedure and continued for 6 to 24 hours afterward to lessen the probability of CIN in patients at risk [86]. Data regarding the use of bicarbonate and N-acetylcysteine remain equivocal [87].
CONCLUSIONS

The key to successful care of the very ill patient with diabetes is careful monitoring of glycemia and fastidious treatment with a continuous infusion of insulin. These patients have defects of normal metabolic regulation, and only attentive treatment can compensate for the diabetes during the metabolic stress of critical illness or surgery. Careful monitoring of blood glucose followed by adjustment of insulin infusion rates minimizes swings to either hyperglycemia or hypoglycemia. Point-of-care glucose determinations make this intensive metabolic care possible not only during an ICU stay but also in the operating room, recovery room, emergency department, and procedural suite. Evidence-based glycemic targets have been developed. Advances in therapy, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 136.4. Although achieving recommended targets demands time and attention, achieving them will minimize the special risks faced by patients with hyperglycemia complicating the stress of severe illness or surgery.

INTRODUCTION

The Acute Metabolic Complications of Diabetes: The Overlap Concept

The most urgent metabolic complications of diabetes are the four diabetic comas: hypoglycemia, diabetic ketoacidosis (DKA), hyperglycemic hyperosmolar syndrome (HHS), and alcoholic ketoacidosis (ethanol-induced hypoglycemia). These diagnostic possibilities must be considered for any lethargic or comatose patient. In addition to being life-threatening conditions, they account for thousands of hospitalizations and substantial costs [1]. Recognition of these diabetic comas is particularly important because these conditions are reversible with appropriate treatment. We use diabetic coma as a generic term that encompasses both frank coma and the milder metabolic abnormalities that precede loss of consciousness. This chapter considers the hyperglycemic crises; hypoglycemia and alcoholic ketoacidosis are discussed in Chapter 138.

Although DKA and HHS are discussed separately, it is important to recognize that metabolic decompensation related to hyperglycemia can take many forms depending on the severity of insulin deficiency, underlying genetic predispositions, and intercurrent illnesses. There is frequent overlap of the clinical phenotypes, and clinicians should be
aware of this concept [1,2]. DKA can occur for a patient with type 2 diabetes; up to a third of patients with HHS have no prior history of diabetes; both DKA and HHS can be complicated by lactic, uremic, or other form of metabolic acidosis, and ketoacidosis itself can occur in the setting of profound hypoglycemia [3]. These metabolic disturbances can overlap to yield both classical DKA and nonclassical presentations of HHS and other ketotic and acidotic states.

For a comatose patient with a blood glucose concentration of less than 50 mg per dL or if for any reason the blood glucose cannot be measured rapidly, the first diagnostic and therapeutic step should be the infusion of 50 mL of a 50% dextrose solution, or when intravenous is not available, injection of 1 mg glucagon intramuscularly or subcutaneously. The hypoglycemic patient who awakens is resuscitated; coma of any other origin is not adversely affected.
DIABETIC KETOACIDOSIS

DKA is comprised of the triad of hyperglycemia, metabolic acidosis, and ketonemia. Any person with diabetes can develop DKA [1], but it most often occurs in those with type 1 diabetes. Before the discovery of insulin, most patients with type 1 diabetes died during an episode of DKA. With current intensive care, overall mortality from DKA has fallen to less than 1%, but is higher among the elderly and those with concomitant major illness [4]. Deaths are associated with intercurrent heart disease or infection of older patients and cerebral edema of younger patients.

Pathophysiology and Etiology

Normal Glucose Homeostasis

After a meal, pancreatic islet β cells release insulin into the circulation, enabling fuels to enter cells and activating enzymes for their storage or metabolism. Glucose enters most tissues only in the presence of insulin; erythrocytes, heart, and brain are exceptions. Glucose is stored in liver and muscle cells as glycogen. Some glucose is metabolized; some is converted into triglycerides.

In adipose tissue, insulin activates lipoprotein lipase, which clears lipoproteins from the circulation, and stores the triglycerides intracellularly. Insulin also inhibits the breakdown and release of previously stored fat. Insulin has similar effects on skeletal muscle, permitting both amino acids and glucose to enter cells for oxidation or storage [5,6].

During starvation, insulin concentrations decrease, catabolic pathways are activated, and stored fuels (glucose, amino acids, and fats) are mobilized to meet energy needs. Liver glycogen provides glucose for only several hours. Muscle glycogen is not directly available due to lack of glucose-6-phosphatase in muscle cells because glucose-6-phosphate cannot cross the plasma membrane. To support plasma glucose, muscle glycogen undergoes anaerobic glycolysis, generating lactate which can cross the plasma membrane and be converted into glucose in the liver. After glycogen stores are exhausted, the liver synthesizes glucose from muscle-derived amino acids through the process of gluconeogenesis [7]. To conserve muscle mass during starvation, glucose consumption is reduced and fatty acids released from adipose tissue become the principal fuel source. Some fatty acids are transformed by the liver into ketoacids [8].

The rate of catabolism is regulated by insulin. As circulating glucose
concentration decreases, insulin concentration also decreases—but never to zero. Low insulin levels permit lipolysis and proteolysis while stimulating gluconeogenesis, all to maintain normal glucose concentrations. Increased glucose concentration stimulates insulin secretion, which in turn reduces or halts catabolism. Precise regulation of insulin secretion, even in the absence of food intake, achieves continuous control of carbohydrate metabolism.

Abnormal Glucose Homeostasis

DKA can be viewed as a “super-fasted” state that occurs when there is insufficient insulin available to regulate carbohydrate metabolism [6]. Without insulin, glucose no longer enters most cells and is neither stored nor metabolized. Glucagon secretion is increased and hepatic glucose production increases without restraint. When the renal threshold for glucose is exceeded (180 to 200 mg per dL), an osmotic diuresis ensues and water and electrolytes are lost. If insulin deficiency persists, the stress-response hormones cortisol, epinephrine, norepinephrine, glucagon, and growth hormone are released and accelerate catabolism. Glucagon excess is responsible for the oxidation of fatty acids to ketone bodies by the liver. When the rate of hepatic ketoacid generation exceeds peripheral utilization, DKA ensues with the life-threatening combination of hyperglycemia, acidemia, ketonemia, loss of free water, and depletion of electrolytes.

The cause of ketoacidosis is insulin deficiency. New-onset type 1 diabetes commonly presents as ketoacidosis, but most cases occur among individuals known to have diabetes. Dietary indiscretion of a person with known treated diabetes may produce classic hyperglycemia, polydipsia, and polyuria but not ketosis. Ketonuria with any hyperglycemic diabetic patient should suggest the presence of DKA. Such patients must be carefully evaluated for the presence of acidemia. Ketoacidosis occurs most often among patients who have omitted their insulin or who have an intercurrent infection [9].

Infection and other stressors produce a state of insulin resistance, in part because of the presence of high inflammatory cytokine levels (in particular, tumor necrosis factor α); infection may be the most common trigger of DKA patients admitted to an intensive care unit (ICU) [10]. Severe stress occasionally causes ketosis among patients with type 2 diabetes [4]. African Americans with type 2 diabetes may be particularly susceptible to the development of ketosis [11,12]. Other factors that can
Precipitate ketosis include acute myocardial infarction, emotional stress, cancer, drugs that interfere with insulin release or action, pregnancy, menstruation, and various endocrinopathies. The use of sodium-glucose cotransporter-2 (SGLT-2) inhibitors (see Chapter 138 on Hypoglycemia) appears to increase the risk of DKA [9,13]. Among those using insulin pumps, catheter site problems resulting in leakage or nondelivery of insulin can precipitate DKA [9]. Occasionally, no precipitating factor can be identified.

Clinical Manifestations

Most patients with DKA are lethargic; about 10% are comatose [14]. They have typically lost large quantities of fluid; their skin, lips, and tongue are dry; and their eyes are soft to palpation. Postural hypotension is common, but shock is rare [15].

Patients with DKA have rapid deep respiration (called Kussmaul), and their breath has a sweet fruity odor. Some patients with new-onset DKA have been misdiagnosed as having psychological hyperventilation [16]. If a patient with DKA is not tachypneic, the physician should suspect that severe acidosis (pH <7.1) may be depressing the respiratory drive [17].

It is important to measure the temperature accurately. Because the patient is hyperventilating, rectal or tympanic temperature should be measured. Patients with DKA do not have fever unless an intercurrent process, usually infection, is present. Similarly, the rare cases of hypothermia in DKA are associated with sepsis [18].

Abdominal pain is common and may be accompanied by a tender guarded abdomen with diminished or absent bowel sounds. DKA should always be excluded when evaluating abdominal pain [19]. What may appear to be a surgical condition will resolve with correction of the acidosis.

Patients with DKA may be nauseous and vomit guaiac-positive coffee grounds–like material. This is probably due to gastric atony, distention, and rupture of mucosal blood vessels. Pleuritic chest pain may also be present. The cause is unknown, but it resolves with treatment of the DKA.

The nose and sinuses of all patients with DKA should be examined. Acute sinusitis and a black intranasal eschar should suggest mucormycosis, an opportunistic fungal infection that disseminates rapidly in acidotic patients. Mucormycosis is often fatal; survival requires prompt diagnosis [20]. DKA as a complication of pregnancy can occur at lower glucose concentrations and progress rapidly. During pregnancy, rates of fetal loss can be high when DKA occurs with new-onset diabetes, when it is due to poor adherence to insulin therapy in preexisting diabetes, or when pregnancy is complicated by infection [21].
Laboratory Diagnosis

Hyperglycemia, acidemia, and ketosis in the appropriate clinical setting are the criteria for the diagnosis of DKA.

**Blood Glucose.** Normal plasma glucose concentration is 60 to 120 mg per dL (3.3 to 6.7 mmol). Whole blood glucose concentrations are 15% to 20% lower. Fingerstick blood glucose determinations are performed on whole capillary blood, and most meters correct for this offset. Calibrated glucose meters suitable for use in the ICU are accurate over a wide range of concentrations, but accuracy is reduced by very high and low glucose concentrations and acidemia; when these conditions are present, results should be confirmed by a clinical laboratory measurement [22]. Meters intended for home use may give less reproducibly accurate results.

Among patients with DKA, blood glucose concentrations of 400 to 800 mg per dL are typical. As many as 15% of cases of DKA present with blood glucose concentrations less than 300 mg per dL [23], and in rare situations, patients present with blood glucose below 180 mg per dL and ketoacidosis [24]. This has been described as euglycemic DKA. Typically, these are younger patients with a high glomerular filtration rate (GFR). Administration of insulin prior to presentation, antecedent food restrictions, and use of SGLT-2 inhibitors can also lower plasma glucose at presentation [4]. More often, the solute diuresis causes dehydration, decreases the GFR, and further increases circulating blood glucose concentration.

**Electrolytes**

**Sodium.** Serum sodium concentration is quite variable in DKA and must be interpreted in the context of serum glucose and lipid concentrations. If extremely abnormal, it needs special attention during management. Large amounts of sodium are lost during the osmotic diuresis of DKA, and the serum concentration does not necessarily reflect this loss. Because sodium resides principally in the extracellular fluid space, elevated sodium concentration may simply reflect the degree of free water loss.

Abnormally low sodium concentrations may be due to the osmotic effect of large amounts of extracellular glucose. The osmotic activity of glucose, drawing free water from the intracellular to the extracellular space, produces a fall of 1.6 mEq per L of sodium for every increase of 100 mg per dL in blood glucose concentration more than 100 mg per dL [25]. The “corrected” serum sodium of a patient with a measured concentration of 135 mEq per L and a glucose concentration of 600 mg per dL is \[1.6 \times (6 - 1) + 135\], or 143 mEq per L. The patient presenting with an elevated serum sodium concentration despite hyperglycemia has a severe total body free water deficit.
It is also important to be certain that abnormally low serum sodium concentrations of DKA patients are not factitious. Sodium resides only in the aqueous phase of plasma and when the nonaqueous constituents such as triglycerides increase substantially, the reported concentration of sodium will be spuriously low with older testing methods. Current technology using “ion-specific” electrodes is unaffected by this problem.

**Chloride.** Chloride concentrations are usually not helpful for the diagnosis of DKA, although they may provide useful information. Hyperchloremia may sometimes represent a more chronic ketoacidotic state [26] and may be associated with slower recovery [27]. Extremely low levels of chloride may result from vomiting [28]. Hyperchloremic acidosis can also occur during recovery from DKA as a consequence of urinary losses of neutralized ketone body salts [29].

**Potassium.** Potassium is the electrolyte that must be watched most carefully and often during therapy. All patients with DKA are at risk of life-threatening hypokalemia during treatment, despite the fact that the serum potassium concentration is usually elevated at presentation [27,30]. This elevation is due to catabolism of tissue, dehydration, and shifts in potassium from the intracellular to the extracellular space as hydrogen ions are buffered. An initially elevated serum potassium concentration should never obscure the fact that total body potassium loss (in the range of 200 to 700 mEq) occurs with ketoacidosis. The greatest potassium loss accompanies the osmotic diuresis of glucose. Additional losses are due to the excretion of ketone bodies as potassium salts, dehydration-induced secondary hyperaldosteronism, and vomiting. Potassium replacement is virtually always necessary early in the course of DKA therapy. It should be started as soon as the potassium concentration is at the upper end of the normal range because continued insulin therapy will invariably cause the potassium concentration to fall further. Normal or low concentrations of potassium early in ketoacidosis reflect a very severe potassium deficit.

**Magnesium.** Like potassium, serum magnesium concentrations among patients with untreated DKA tend to be elevated initially, but they fall with subsequent hydration.

**Bicarbonate.** Serum bicarbonate concentrations are low with ketoacidosis [17] because of neutralization of ketone bodies, which are acids. Bicarbonate buffer in the extracellular compartment represents the first line of defense in acid-base homeostasis. The process is summarized
in Figure 137.1. Hydrogen ion (H\(^+\)) from ketoacids is neutralized by bicarbonate, producing carbonic acid, water, and CO\(_2\). As CO\(_2\) is cleared through the lungs, the neutralized salts of the ketone bodies are excreted in the urine. Among patients with established DKA, the serum bicarbonate concentration is typically less than 15 mEq per L, and can be much lower.

**Phosphorous.** Elevated serum phosphate concentrations are common with untreated DKA; the mechanism is not clear. After therapy, there is a precipitous decline to subnormal levels. It has been estimated that as much as 1 mmol per kg of phosphate is lost during DKA. Hypophosphatemia of less than 0.5 mmol per L has been described for both DKA and HHS [31].

**Acidosis.** Arterial blood gas and pH measurements are essential for the management of all but the mildest cases of DKA. The arterial pH in DKA is almost always less than 7.3. If arterial samples cannot be obtained, venous or capillary samples may be used, although they provide less information [32]. DKA classically presents as an anion gap acidosis. The anion gap should be calculated for all acidemic patients (Table 137.1). In addition to confirming the diagnosis of DKA, the anion gap can be used together with plasma ketone measurements to obtain important additional insight into the nature and severity of a given case [33]. More
chronic ketoacidotic states may be associated with hyperchloremic rather than anion gap acidosis [26], probably as a consequence of the loss of neutralized ketone body salts [29]. Rare cases of DKA are complicated by intercurrent metabolic alkalosis, most often from severe vomiting [28,34].

*a Normal Anion Gap is less than 12 mEq per L for most laboratories. Refer to your lab normal range.

*b Normal osmolality: 285 to 295 mOsm per kg. BUN, blood urea nitrogen.

### Plasma Ketones and $\beta$-Hydroxybutyrate

Plasma ketones should be measured for all patients with diabetes who appear critically ill or exhibit signs of dehydration at the time of presentation. When the nitroprusside test is used, the results are usually expressed as the highest dilution of serum that gives a positive reaction. This test is always positive (>1:2 dilution) during DKA, but its result may not reflect the full extent of ketogenesis. This is because the test measures only acetoacetate (AcAc) and acetone. It does not measure $\beta$-hydroxybutyrate (BOHB), which, although a “ketone body,” is a hydroxyl acid and not a ketone (Fig. 137.2). Normally, the BOHB-to-AcAc ratio is 3:1, but acidosis increases the ratio to 6:1 or even 12:1 as pH decreases. The BOHB-to-AcAc ratio at pH 7.1 is at least 6:1.

![Biochemical interrelationships of the ketone bodies. Acetoacetate and acetone are ketones, whereas $\beta$-hydroxybutyrate, although a “ketone body,” is $\beta$-hydroxy carboxylic acid and not a ketone. NAD$^+$, nicotine adenine dinucleotide; NADH, reduced form of NAD.](image)

p. 1270

p. 1271
BOHB can be measured directly, and the test is available from many hospital laboratories. Measurement of BOHB concentration, if the result is available rapidly, can also be used to establish the diagnosis of DKA. The advantage of BOHB measurement derives from the fact that it is the major ketone body and its concentration is a better indicator of the severity of ketoacidosis.

The results of plasma ketone, BOHB, anion gap, and arterial pH measurements can be used to determine whether a pure or mixed anion gap acidosis is present. The highest positive ketone dilution is multiplied by 0.1 mmol per L to obtain an estimate of AcAc concentration; the BOHB can be measured directly. If a patient’s anion gap as calculated in Table 137.1 is greater than the estimated contribution of ketone bodies (AcAc plus BOHB), the presence of an additional unmeasured anion should be considered (e.g., lactate, salicylate, uremic compounds, methanol, or ethylene glycol; see Chapter 198).

Ketone body measurements are also useful for monitoring the resolution of DKA. During severe acidosis, ketones as measured by the nitroprusside reaction initially rise rather than fall as the acidosis improves. This is due to conversion of BOHB back to AcAc. Clearance of ketone bodies occurs slowly; frequent measurement of ketones and BOHB is generally unnecessary.

It is worth noting that certain home blood monitors have the capacity to measure not only glucose but also “ketones.” These meters measure BOHB rather than AcAc using strips distinct from those used to measure glucose. They can warn patients of impending or established ketoacidosis prior to hospital presentation.

**Blood Urea Nitrogen and Creatinine.** The blood urea nitrogen (BUN) of patients with DKA is typically elevated to values between 25 and 50 mg per dL due not only to prerenal azotemia from volume depletion but also from increased ureagenesis. Patients with DKA are in a state of uncontrolled gluconeogenesis; the large quantities of amino acids released from muscle for conversion to glucose produce hyperaminoacidemia. These amino acids increase substrate availability for ureagenesis. Although the serum creatinine concentration usually reflects the degree of dehydration and prerenal azotemia during DKA accurately [35], spurious elevations occasionally occur because AcAc interferes with some older creatinine assays [36].

**Complete Blood Count.** Hematocrit and hemoglobin during DKA are usually high and in proportion to the degree of dehydration. Low values suggest preexisting anemia or acute blood loss. A characteristic hematologic finding during DKA is leukocytosis. The white cell count can be elevated to 20,000 or more with a shift to the left in the absence of infection, but concurrent infection should be actively sought whenever
the white count is significantly elevated \[14,37]\.

**Triglycerides.** Insulin deficiency impairs clearance of lipid from the circulation and accelerates hepatic production of very low-density lipoprotein \[5\]. During DKA, there is marked elevation of serum triglyceride concentrations that may be clinically obvious in the form of lactescent serum. With insulin therapy, this biochemical derangement reverses. If a patient can eat during the onset of DKA, hyperchylomicronemia may also be present.

**Urine.** Urinary glucose and acetone should be measured. If pyuria is present, a urine specimen should be sent for culture and sensitivity. Catheterization should be avoided unless the patient is comatose or anuric. A pregnancy test should be performed for women of childbearing age, as pregnancy can precipitate DKA.

**Serum Amylase and Lipase.** Serum amylase and lipase concentrations are sometimes elevated during acute ketoacidosis, but they do not necessarily imply exocrine pancreatic disease \[38,39\]. For some cases, the amylase may be of salivary gland origin.

**Other Laboratory Findings.** Uric acid concentrations may be elevated during acute DKA \[40\] as a result of impaired renal function or competition from ketone bodies at sites of tubular secretion. Hepatic enlargement with fatty infiltration of parenchymal cells may occur during acute DKA. Increased levels of C-reactive protein and interleukin-6 may be indicative of underlying infection precipitating DKA \[41\].

**Treatment**

Patients with severe DKA should be hospitalized in an ICU. Delaying intensive care greatly increases morbidity, and detaining patients in the emergency room long after the diagnosis is established should be avoided. Some hospitals are able to treat DKA outside the ICU with protocols involving close monitoring, and report good outcomes \[42\]. Treatment should be directed at three main problems—fluid deficits, electrolyte abnormalities, and insulin deficiency—in that order \[43\]. Table 137.2 highlights the key components of therapy.

**Recording of Data**

The comprehensive flow sheet of vital signs, laboratory data, and treatment that is part of the modern electronic ICU greatly enhances management. In the absence of electronic records, a comprehensive paper flow sheet is essential to follow the responses to therapy. Standardized protocols may improve efficiency of care.
**Fluid Replacement**

Fluid and electrolyte therapy always takes precedence over insulin administration during the treatment of DKA. As described later in the “Complications” section of this chapter, insulin administration before volume and potassium repletion can cause shock and arrhythmias [44]. The free water deficits of adults with DKA generally range between 5 and 11 L, typically about 100 mL per kg, and is due primarily to the osmotic diuresis of hyperglycemia [43,45]. Vomiting and hyperventilation may also contribute to water losses. Initial fluid resuscitation should be an infusion of 0.9% saline. Approximately 2 L or 25 mL per kg should be given during the first hour to restore blood volume, stabilize blood pressure, and reestablish urine flow. Another liter of 0.9% saline can typically be given during the next 2 hours. The subsequent rate of fluid replacement depends on individual clinical circumstances. During the first 24 hours, 75% of the estimated total water deficit should be replaced. Urine flow should be maintained at approximately 30 to 60 mL or 0.5 mL/kg/h. Fluid replacement after the first 2 L may be changed to hypotonic 0.45% saline when hypernatremia is present [46].

**Electrolytes**

**Sodium, Chloride, and Potassium.** Sodium and chloride are replaced together with free water as just described. Potassium must be added to the saline. Because serum potassium concentration does not accurately reflect total body potassium, replacement should be initiated early during treatment. Until the serum potassium concentration is known, replacement should be carried out cautiously. The recommended initial repletion rate is 20 mEq per hour as KCl or K$_3$PO$_4$. When the serum value is known, the rate of potassium administration can be adjusted. If a nasogastric tube is in place, electrolyte losses due to gastric suctioning must also be considered. Typical potassium deficits in DKA are 3 to 5 mEq per kg, but if hypokalemia or normokalemia is present at the time of admission, the deficit may be much higher, up to 10 mEq per kg.

Potassium concentration often falls precipitously after starting therapy. K$^+$ shifts from the extracellular to the intracellular space in the presence of glucose and insulin. As acidemia resolves, buffered intracellular H$^+$ is exchanged for extracellular K$^+$, further lowering the serum potassium concentration. A sudden reduction in serum potassium concentration can cause flaccid paralysis, respiratory failure, and life-threatening cardiac arrhythmias. If a patient in mild DKA is alert and able to tolerate liquids,
potassium should be given orally.

**Phosphate.** Depletion of phosphate occurs with DKA. Initially, the concentration of phosphate is elevated, but levels may decrease to less than 1 mmol per L within 4 to 6 hours of starting insulin treatment. Persistent severe hypophosphatemia can cause neurologic disturbances, arthralgias, muscle weakness with respiratory impairment, rhabdomyolysis, and liver dysfunction [47].

Except when hypophosphatemia is severe (≤1.0 mg per dL), however, the need for phosphate replacement during treatment of DKA may be more theoretical than real. No studies have demonstrated that replacement of phosphate affects the course or outcome from ketoacidosis [48,49].

For treating severe hypophosphatemia, potassium phosphate (20 mEq K⁺; 16 mmol PO₄³⁻) can be added to replacement fluids in place of KCl. Because phosphate deficits during DKA average only 1.0 mmol per kg, it is rarely necessary to administer more than one 5-mL ampule of potassium phosphate. Thereafter, potassium should be replaced as KCl. The hazards of parenteral phosphate administration include hypomagnesemia, hypocalcemia, and metastatic calcification [50]. If a patient with DKA can tolerate oral medication, phosphate-containing antacids (e.g., Neutra Phos) can be given.

**Bicarbonate.** Despite the presence of a low serum bicarbonate concentration and severe acidemia, most authorities now concur that there is no need for the routine use of bicarbonate therapy for DKA [51–55]. Neutralization is intuitively appealing, but fluid and electrolyte replacement alone will ameliorate the acidosis, and bicarbonate therapy may produce adverse effects. These include severe acute hypokalemia [56], late alkalosis due to paradoxical cerebrospinal fluid acidosis [57], a shift in the oxygen dissociation curve to the left that results in tissue hypoxia and lactic acidosis [58], and increased hepatic ketogenesis [53]. Among children, bicarbonate therapy may increase the risk of cerebral edema [59]. Bicarbonate replacement during DKA should be used only when hypotensive shock is unresponsive to rapid fluid replacement [60], buffering capability is completely exhausted, respiratory responses are maximal, and acidemia is worsening [43], or for those with advanced preexisting renal dysfunction [61]. Even in these circumstances, bicarbonate can only “buy time” until metabolic treatment reverses the acidosis. On those rare occasions when it may possibly be beneficial, two ampules of sodium bicarbonate (100 mEq total) in 400 mL of sterile
water with 20 mEq KCL should be infused over 2 hours [4,61].

**Magnesium.** Hypermagnesemia may occur early in the course of DKA [62], but serum Mg\(^{2+}\) concentrations generally return to normal without specific treatment. For some patients, Mg\(^{2+}\) stores may be depleted, and hypomagnesemia may rarely lead to cardiac arrest [63]. Dysrhythmia should alert the physician to the possible need for magnesium supplementation.

**Insulin**

Insulin therapy for DKA is essential but should be instituted only after fluid and electrolyte resuscitation is underway [43]. Continuous low-dose infusion after an intravenous loading dose is the preferred method [64]. For adults, we recommend a bolus of 10 U of short-acting insulin followed by a continuous intravenous infusion starting at 5 to 10 U per hour. For children, the recommended initial bolus is 0.1 U per kg of body weight and the infusion rate is 0.1 U/kg/h [65–67]. If for some reason a continuous infusion cannot be given, an initial intravenous bolus of 10 units of short-acting insulin followed by repeated subcutaneous or intramuscular short-acting insulin injections can be used. Regular (crystalline) insulin is typically used for intravenous infusions; semisynthetic rapid-acting insulins approved for intravenous administration offer no advantage by this route. The onset of action of intravenous regular insulin occurs within minutes; bolus doses peak within 30 minutes, and the duration of action is 2 to 3 hours.

When DKA is treated with frequent subcutaneous insulin injections, very short-acting analogues may be advantageous because of their rapid onset of action. Their shorter duration of action may, however, require more frequent monitoring of blood glucose concentration. The safety and efficacy of repeated subcutaneous injections of rapid-acting insulin analogues every 1 to 2 hours for the treatment of uncomplicated DKA is well documented [68].

Insulin for infusion should be added to 0.45% saline (at a concentration of 0.5 U per mL), and the container swirled before use. Blood glucose concentration should be measured every 1 to 2 hours after starting the infusion. If the glucose concentration has not decreased by 50 to 75 mg/dL/h, the insulin infusion rate should be doubled. When the glucose concentration has fallen by more than 150 mg per dL, the infusion rate should be decreased by 50%, but it should never be stopped.

Once the plasma glucose concentration approaches 200 mg per dL, glucose infusion (D5W) or D5 1/2NS should be started, and the insulin infusion rate should be adjusted to \(\approx 1.0\) U per hour to maintain insulinization and inhibit ketogenesis. Following this, the goal should be
to maintain the blood glucose concentration between 150 and 200 mg per dL, by adjusting the glucose infusion and insulin infusion rates until DKA resolves. Insulin should never be stopped entirely during the treatment of DKA, even if the infusion rate is reduced to only 0.5 U per hour or less. This is particularly important for children with DKA because their high GFR and high rate of urinary glucose excretion can lead to a low blood glucose concentration before ketone production has been reversed by insulin administration.

As noted above, resolving DKA is often accompanied by an increase in plasma ketones (principally AcAc) as BOHB is reoxidized. Total ketone bodies (AcAc plus BOHB) slowly fall throughout treatment, and the increase in measured ketones is transient. An increase in conventionally measured “plasma ketones” during the early hours of DKA treatment does not necessarily mean that treatment is inadequate and that more insulin is needed. The entire clinical picture must be assessed, and when the acidosis and hyperglycemia are resolving, the rise in ketones should be interpreted as a sign of improvement.

Complications

The morbidity and mortality associated with DKA are proportional to the severity of coma and acidemia at the time of presentation. Many complications can occur despite appropriate therapy.

Hypotension and Shock

Hypotension is an important complication of DKA. It is usually caused by volume depletion, and normally fluid replacement alone will reverse it [69]. Persistent hypotension should prompt consideration of fluid shifts, bleeding, severe acidosis, hypokalemia, arrhythmia, myocardial infarction, sepsis, and adrenal insufficiency.

When insulin is administered to a patient with DKA, both glucose and water move to the intracellular space. Blood pressure may then fall as extracellular and intravascular volumes decrease. Increasing the rate of fluid replacement can usually reverse this.

If shock persists despite fluid replacement, occult blood loss should be considered. Patients with gastric ulcer, colitis, or hemorrhagic pancreatitis can bleed into the gut lumen or peritoneum. Physical examination and an inappropriately low hematocrit in the face of dehydration are clues to this complication.

A shift in K+ from the extracellular to the intracellular fluid space after insulin administration can lower serum potassium concentration and cause cardiac arrhythmias.

Patients with hypotension and increased central venous pressure
should be evaluated for heart disease. Myocardial infarction is the most common finding, but other conditions such as cardiac tamponade and diastolic cardiac dysfunction can occur. Myocardial infarction is a common complication of long-standing diabetes, and its classic symptoms may be less obvious in the diabetic population. Patients in DKA who have had a myocardial infarction have a poorer prognosis [70].

Gram-negative sepsis is another cause of shock in ketoacidosis [60]. Pyelonephritis and pneumonia are common among such cases and must be treated appropriately when encountered. Ketoacidosis per se does not cause fever.

It is not uncommon for patients with type 1 diabetes to have other autoimmune diseases, and adrenal insufficiency should be considered among cases of ketoacidosis with refractory shock. The stress of DKA may uncover a state of partial adrenal insufficiency requiring glucocorticoid replacement.

The initial approach to the patient in shock is additional fluid replacement. (See Chapters 39 and 37 for a detailed discussion of the subsequent management of this problem.) Thereafter, further diagnostic procedures are necessary. Cardiac rhythm, respiratory, and hemodynamic monitoring is recommended.

**Thrombosis**

The dehydration and intravascular volume contraction common with DKA may activate coagulation factors [71]. Thrombosis of cerebral vessels and stroke are recognized complications of DKA. Some authorities suggest the routine use of low-dose heparin during the management of DKA, but there are no controlled studies to document its efficacy [72].

**Cerebral Edema**

Subclinical brain edema may be common during DKA [73], but clinically important cerebral edema is a rare complication among adults. It occurs more commonly among children [66], with a reported frequency of 0.3% to 0.5% in pediatric cases of DKA [65,74]. Cerebral edema has been associated with very high mortality (24%) [74], but a recent retrospective analysis shows current mortality rates are less than 10% [75]. It usually occurs a few hours after the initiation of therapy. Children who develop cerebral edema during treatment for DKA may initially have a relatively normal serum osmolality and then experience a progressive decline in
serum sodium concentration [76]. Treatment with bicarbonate increases the risk of cerebral edema among children with DKA who present with azotemia and a low PCO₂ [59]. Greater baseline acidosis, higher potassium and urea concentrations, and large volumes of administered fluids are also risk factors for cerebral edema [77].

The exact mechanism of cerebral edema is unknown, but it may involve a combination of fluid shifts, thrombosis of intracerebral vessels, and effects on ion exchange mechanisms [61,78]. The most effective treatment for cerebral edema is probably mannitol [75,79], although hypertonic saline is being used with increasing frequency [75,80]. Steroids are not recommended [81,82]. Unfortunately, even when diagnosed early, cerebral edema may cause permanent neurologic damage or death.

**Renal Failure**

Hyperglycemic patients given intravenous fluids should have brisk urine flow. Patients with DKA who do not void within a few hours of therapy should be considered oliguric. A common cause of oliguria is postrenal obstruction and bladder scanning is recommended. A dilated atonic bladder is common in comatose patients and even more common in diabetic patients with severe neuropathy and DKA. Occasionally, patients with DKA precipitated by pyelonephritis develop acute tubular necrosis. Acute renal failure in the absence of infection is an uncommon complication of DKA [83].

**Recurrent Diabetic Ketoacidosis**

If ketoacidosis reappears for a patient who has received adequate amounts of insulin, infection or a severe contra-insulin state (e.g., Cushing’s syndrome) should be suspected. More commonly, the problem is iatrogenic. The physician treating DKA notes that the blood glucose concentration has fallen, mistakenly assumes the condition has been cured, and discontinues insulin treatment. Because the duration of action of intravenous insulin is brief and these patients make no insulin, ketone production resumes and ketosis soon recurs [2]. Insulin infusions should be continued, if only at 0.5 to 1 U per hour, until the patient is well enough to be switched to subcutaneous injections of long-acting insulin. The intravenous infusion of insulin should be continued for 2 to 3 hours after the first subcutaneous injection of intermediate-acting or long-acting insulin is given so that the subcutaneous insulin has time to appear in the bloodstream. Cases of insulin-resistant DKA with recurrent hyperglycemia that respond to treatment with insulin-like growth factor I have been described [84], but these are extremely uncommon.
Low Blood Glucose Concentration

The blood glucose concentrations during DKA usually decrease rapidly as a result of renal excretion as soon as fluid is administered and urine flow is established [69]. After insulin is given, glucose is metabolized as well as excreted, and blood glucose concentrations may fall rapidly. The physician must be alert to the possibility of precipitous reductions in glycemia and frequent monitoring of blood glucose is recommended. To avoid cerebral edema, the goal of the first 24 hours of DKA treatment is a blood glucose concentration not less than 200 mg per dL.

When the blood glucose concentration falls to 200 mg per dL, a D5 containing intravenous fluid should be administered together with insulin [85]. Dual therapy inhibits ketone production while precluding hypoglycemia. For the first 24 hours of treatment, continuous intravenous infusion of insulin is recommended.

Follow-Up Care of Diabetic Ketoacidosis

After a patient has recovered from DKA, the physician’s goal should be the prevention of further episodes [86]. This requires the identification of any precipitating factors. Any lack of education regarding diabetes should be remedied.
HYPERGLYCEMIC HYPEROSMOLAR SYNDROME

Severe hyperglycemia, dehydration, and coma have long been known to occur in the absence of significant acidosis or ketonemia among older patients with diabetes [87]. This syndrome is designated as HHS. Mortality with HHS has historically been high, on the order of approximately 50%, but increasing recognition and improved ICU-based treatment have substantially improved this figure; mortality more recently is on the order of 15% [70,88]. With optimal care, HHS managed in an ICU setting can carry a relatively favorable prognosis. Of note is the fact that, with the increasing prevalence of obesity and type 2 diabetes among children, a similar disorder is being reported for the pediatric population [89,90]. The syndrome can be the initial presentation of type 2 diabetes and, in the United States, may occur with disproportionate frequency among African American youth.

Pathophysiology and Etiology

The pathophysiology that gives rise to HHS requires that three interrelated elements be present: insulin deficiency, renal impairment, and cognitive impairment.

Insulin Deficiency

Relative lack of insulin is the fundamental defect in HHS. Patients have sufficient insulin to inhibit ketone body formation but not enough to prevent hyperglucagonemia, glycogenolysis, and gluconeogenesis [91]. The resulting hyperglycemia induces an osmotic diuresis, with resultant fluid and electrolyte losses.

Paradoxically, venous insulin concentration levels of patients with HHS are comparable with those sometimes observed in DKA [92]. Animals with experimentally induced HHS have portal insulin concentrations higher than those of animals with experimental ketoacidosis [93]. The data suggest that partial insulinization of the liver with HHS enables affected patients to metabolize free fatty acids and thereby avoid ketogenesis in the face of severe hyperglycemia. Additional data indicate, however, that hepatic insulinization alone cannot account
for the absence of ketosis in HHS. Ketone bodies can be induced when medium-chain triglycerides (precursors of fatty acids) are administered to animals with an experimental HHS syndrome [94]. The result suggests that patients with HHS would produce ketones despite hepatic insulization if enough substrate in the form of free fatty acids were present. Their resistance to ketosis must therefore depend on limited availability of circulating free fatty acids [95].

The low concentrations of free fatty acids during HHS may be due to relatively low concentrations of lipolytic hormones [96] including growth hormone and cortisol, concentrations of which are lower in HHS than in DKA. Another explanation is that hyperosmolality itself inhibits the release of free fatty acids [97]. Additional unidentified factors may play a role.

**Renal Impairment**

Some degree of renal impairment accompanies all cases of HHS. Younger patients with diabetes have a normal GFR and, even in the event of DKA, filter enough glucose into the urine to prevent extreme hyperglycemia. In contrast, typical patients with HHS are older. Their renal blood flow and GFR are reduced, and they cannot readily excrete a glucose load. When they become hyperglycemic, the glucose is neither metabolized nor excreted. It remains in the extracellular fluid space. The resulting increase in osmolality, together with the decreased GFR, causes still less glucose to be excreted (Fig. 137.3). It has been suggested that, among children with baseline normal renal function, extreme hyperglycemia may be precipitated by intake of large amounts of sugary drinks to compensate for urinary fluid losses [89].

![FIGURE 137.3](image)

**FIGURE 137.3** Interrelationship of blood glucose concentration, glomerular filtration rate (GFR), and renal excretion of glucose. This diagram illustrates the importance of dehydration and diminished GFR in the development of extreme hyperglycemia in hyperglycemic hyperosmolar syndrome (HHS). The normal individual, with normal GFR and
normoglycemia, is never glycosuric. A diabetic individual with normal renal function and normal thirst response may become hyperglycemic if glycemic control is poor, but the high GFR leads to glycosuria, and severe hyperglycemia does not usually develop. In a patient with HHS, in contrast, osmotic diuresis and impairment of thirst response lead to progressive deterioration in GFR. The kidney’s ability to excrete glucose declines and extreme hyperglycemia develops.

The underlying renal abnormality of HHS may be prerenal, renal, or postrenal. The common result is that affected patients are unable to compensate for the hyperglycemia with an osmotic diuresis. The result is an extremely high glucose concentration. Severe hyperglycemia itself can cause prerenal azotemia because glycosuria causes a hypotonic osmotic diuresis resulting in urinary loss of free water. If not replaced orally, this loss causes reductions in intravascular volume and renal perfusion.

Cerebral Impairment

Hyperglycemia leading to hyperosmolality normally activates thirst. The combination of mild diabetes and azotemia does not lead to HHS unless the affected individual does not drink sufficient water to prevent hyperosmolality. Invariably, HHS involves acute or chronic impairment of cerebral function. A common history involves an elderly patient with impaired cognitive function due to cerebrovascular disease, dementia, or central nervous system—depressant medications. This impairment may involve either concurrent impairment of the normal thirst mechanism or an inability to respond to thirst due to speech or motor deficits. Patients with trauma or burns have large insensible water losses, are often unable to drink, and are also susceptible to HHS in the absence of adequate parenteral fluids.

Animal studies confirm that fluid restriction is necessary to produce an HHS-like disorder. Diabetic rats do not develop HHS unless they are deprived of water [98]. Decreased thirst leads to increased dehydration, increased stupor, and further decreases in fluid intake. Other factors, such as angiotensin, may also be involved [99].

Interrelationships

To summarize, three interrelated factors are required for HHS. Insulin deficiency leads to hyperglycemia and glycosuria. Impaired renal function exaggerates the hyperglycemia and leads to hyperosmolality. Decreased
free water intake precludes dilutional compensation and further exacerbates prerenal azotemia. Together, these three factors produce dehydration and the hyperosmolar hyperglycemic state (Fig. 137.4).

![FIGURE 137.4](image)

**Pathogenesis of hyperglycemic hyperosmolar syndrome (HHS).** Three interrelated factors give rise to HHS: insufficient insulin leads to hyperglycemia and glycosuria, impaired renal function exaggerates the hyperglycemia and hyperosmolality, and impaired cognition leads to decreased free water intake. Together, these factors lead to dehydration and the hyperosmolar hyperglycemic state.

The severe dehydration that occurs with this syndrome is due to the osmotic diuresis of glucose in the absence of compensatory free water intake. Dehydration, in turn, leads to hemoconcentration, setting the stage for severe prerenal azotemia, thrombosis, and shock. As glucose and osmolality rise, cerebral function is progressively compromised. Coma ensues when the serum osmolality is 350 mOsm per kg [100]. Severe HHS may take several days to develop.

**Clinical Findings in Hyperglycemic Hyperosmolar Syndrome**

Patients who develop HHS are typically middle aged or elderly [101,102]. The syndrome occurs less commonly among younger patients and rarely among infants [90] and may represent an overlap with DKA [2]. Patients
often have a history of type 2 diabetes treated with diet and/or oral hypoglycemic agents. There may be a prodrome of progressive polyuria and polydipsia and, occasionally, polyphagia lasting days to several weeks.

Most patients have underlying diseases. Renal and cardiovascular disorders are the most common. Other intercurrent problems include infection, myocardial infarction, stroke, hemorrhage, and trauma [102]. Additional predisposing factors include dialysis [103], hyperalimentation [104], and medications. Diazoxide [105], phenytoin [106], propranolol [107], immunosuppressive agents [108], cimetidine [109], and the antipsychotic drugs clozapine and olanzapine [110,111] all impair insulin secretion or action and have been implicated as causes of HHS. The disorder has also been associated with treatment of HIV with the nucleoside analogue didanosine [112] and lithium-induced diabetes insipidus [113,114].

Fever is a common finding during HHS even in the absence of infection, but infection must be rigorously excluded for all cases. Patients may have hypotension and tachycardia due to dehydration, and they frequently hyperventilate. Neurologic manifestations include tremors and fasciculations. Mental status ranges from mild disorientation to obtundation and coma depending on the degree of abnormalities in osmolality and perfusion [115]. Up to a third of patients with HHS may seize [116], and many in this group are misdiagnosed as having primary intracerebral disease. Once treatment has been instituted, neurologic symptoms may clear rapidly. The hyperventilation may reflect lactic acidosis, a common complication of severe dehydration and hypotension. Rapid respiration of a hyperglycemic patient does not always imply ketoacidosis.

**Diagnosis**

The key to the diagnosis of HHS is the demonstration of hyperglycemia and hyperosmolality without significant ketosis in the appropriate clinical setting.

**Blood Glucose Concentration**

Blood glucose concentrations in HHS are generally higher than in DKA, usually greater than 600 mg per dL. Values as high as 2,000 mg per dL occur.

**Acetone**

Most patients in HHS are not ketonemic. Serum acetone levels are
usually normal or only slightly elevated, seldom exceeding a dilution of 1:2. Occasionally, patients with HHS develop a severe intercurrent metabolic acidosis. In these very ill patients, a severe hyperosmolar state may overlap with ketoacidosis. Such cases are uncommon.

---

Osmolality

Serum osmolality of comatose patients is usually more than 350 mOsm per kg. It can be measured directly in the laboratory but is easily and quickly approximated from BUN, sodium, potassium, and glucose concentrations as shown in Table 137.1.

Acid–Base Balance

Most patients with HHS are only mildly acidotic. Serum bicarbonate concentration and arterial pH are usually close to normal. The average pH is about 7.25 before treatment, and HCO₃⁻ is typically ≥15 mEq per L. The acidemia most often represents either mild lactic acidosis or uremic acidosis. When a significant anion gap is present (see Table 137.1), other causes of acidosis should be considered. These include salicylate, methanol, and ethylene glycol ingestions.

Renal Function

As outlined above, renal function is always impaired among patients with HHS. In addition to any preexisting renal disease, dehydration induces prerenal azotemia, and the ratio of BUN to creatinine is usually greater than 30:1. BUN and creatinine should be repeated after treatment to determine the degree of intrinsic renal impairment.

Electrolytes

The serum sodium concentration during early HHS is highly variable, ranging between 100 and 180 mEq per L. Hyponatremia may result from the dilutional effect of osmotically active glucose among patients with high free water intake in the face of impaired renal function. As mentioned previously, for each 100 mg per dL increase in blood glucose in excess of 100 mg per dL, serum sodium concentration falls approximately 1.6 mEq per L. When severe hypotonic fluid losses occur in the later stages of HHS, patients may become hypernatremic. Because
sodium remains in the extracellular fluid compartment, this electrolyte should be followed to assess the state of hydration. Frequent calculations of the corrected sodium need to be done to properly guide the choice of fluids and rates for rehydration [117].

Serum potassium concentration during HHS syndrome is also variable. It may range from 2.2 to 7.8 mEq per L. Hypokalemia requires immediate potassium replacement. As mentioned later, serum potassium concentrations decrease after treatment with insulin is begun. Hyperkalemia often responds to fluid replacement and improvement in urinary output. Patients with HHS, like those with DKA, lose substantial quantities of electrolytes.

**Treatment**

**Overview**

The best treatment for HHS is prevention. The condition can be avoided by periodic attention to blood glucose control and mental status. Susceptible individuals are those with mildly impaired glucose metabolism. They are often the elderly who live alone. They may be hospitalized in patients who have experienced trauma, undergone extensive surgery, or been placed on hyperalimentation regimens. They may also be residents of nursing homes, although improvements in care appear to have reduced this risk [102]. Individuals in all of these settings can be at risk of hyperglycemia and hyperosmolality. When HHS does occur, continuous vigilance for monitoring the details of the patient’s clinical progress at the bedside is the key to achieving a successful outcome.

**Fluid Replacement**

Patients with HHS are, without exception, profoundly dehydrated. Within the first 2 hours, 1 to 2 L of 0.9% saline should be given. Normal saline is recommended, even if hypernatremia is present, to expand the extracellular fluid compartment rapidly. After initial volume expansion and restoration of normotension, subsequent treatment for dehydration in this syndrome emphasizes free water replacement. The osmotic diuresis of glucose produces free water loss in excess of solute loss. The initial infusion of normal saline must never be overlooked, however, because it rapidly expands the extracellular compartment and helps reestablish adequate perfusion (see Table 137.2). The corrected serum sodium can be used to help decide when the switch from 0.9% saline to 0.45% saline should be made.

injections of fast-acting insulin every 1–2 h to be as effective as intravenous infusion of regular insulin [68].

Treatment of the diabetic comas has evolved incrementally over many decades. This table summarizes the validation of key components of therapy. DKA, diabetic ketoacidosis; HHS, hyperglycemic hyperosmolar syndrome.

The typical HHS patient requires 6 to 8 L of fluids (100 to 200 mL per kg) during the first 12 hours of treatment. The rate of fluid administration must be adjusted as appropriate to the patient’s clinical status. Elderly patients with cardiovascular impairment may require less aggressive replacement.

Electrolytes

As soon as adequate urine flow has been established and the degree of hypokalemia estimated, potassium supplementation should be added to intravenous fluids. During the initial phases of therapy, serum potassium concentration should be checked frequently and the electrocardiogram monitored for changes in morphology and rhythm. A sudden fall in serum potassium concentration frequently accompanies the initiation of insulin therapy [95]. Cardiac arrhythmias induced by hypokalemia may be irreversible, particularly among the elderly. The potassium deficit of HHS can be ≥5 mEq per kg, but generally, the magnitude of the loss is not as great as that encountered during DKA [118].

Insulin

Most patients with HHS are more sensitive to insulin than are patients with DKA [95]. In addition, blood glucose concentration in HHS can fall rapidly when urine output is reestablished after volume expansion with saline. The combination of insulin sensitivity and glucose diuresis puts patients with HHS at risk of sudden unexpected hypoglycemia. Treatment with insulin is essential but should be instituted with careful monitoring and only after fluid and electrolyte resuscitation is underway.

Only short-acting insulin should be used. Continuous infusion is now standard but must be used with great caution. We do not recommend an initial intravenous insulin bolus. For the infusion, we recommend a starting dose of 1 to 5 U per hour, depending on individual circumstances. This dose is sufficient to insulinize the patient and is usually not high enough to cause severe hypoglycemia. If continuous insulin infusion therapy is not possible, treatment should be with boluses of intravenous regular insulin. The initial dose should not exceed 10 to 30 U. Boluses should be given every 2 to 4 hours, with dose adjusted on the basis of
blood glucose determinations.

As emphasized repeatedly, normalization of glucose is not the primary goal of treatment; fluid and electrolyte resuscitation take precedence and often improve glycemia substantially before any insulin is given. An attempt should be made to maintain blood glucose concentration near 250 mg per dL for the first 24 hours. Rapid fall in blood glucose concentration correlates with the development of cerebral edema [100,119].

Complications

Hypotension

When insulin is administered to patients with HHS syndrome, glucose shifts from the extracellular to the intracellular compartment. Because glucose is osmotically active, the movement of glucose intracellularly draws free water from the extracellular compartment. The rapid intracellular movement of free water compromises intravascular volume and may precipitate hypotension and shock [120]. The use of normal (0.9%) saline for initial volume replacement helps prevent hypotension. The higher osmolality of normal (308 mOsm per L) compared with half-normal (154 mOsm per L) saline reduces the osmotic effect of the glucose shifts that follow insulin administration [121].

The magnitude of the fluid shifts that can be induced by insulin was illustrated in a dramatic case report. A patient with congestive heart failure and preexisting renal disease was found to have severe hyperglycemia. Because fluid replacement was contraindicated, the patient was treated with insulin alone. The insulin treatment resulted in a shift in fluid from the extracellular to the intracellular compartment sufficient to ameliorate the congestive heart failure [122].

Cerebral Edema

Blood glucose concentrations should never be reduced precipitously. Rapid reduction is a major contributor to the development of cerebral edema and a fatal outcome in HHS. The exact cause of cerebral edema in HHS is unknown, but animal studies suggest that neuronal intracellular osmolality increases in HHS. The osmotically active solute has not been identified. The term idiogenic osmoles is used to describe these uncharacterized, osmotically active, nondiffusible substances [123]. They draw water into neurons when the extracellular osmolality drops as a result of the intracellular movement of glucose. This is followed by severe edema, increased intracranial pressure, and disturbed hypothalamic function.
Thrombosis

Large vessel thromboembolic events are an important cause of mortality from HHS. Severe dehydration and hyperosmolality lead to reduced cardiac output and hyperviscosity, predisposing to venous and arterial thrombosis. Use of low-dose heparin prophylaxis is recommended for high-risk patients [124].
CONCLUSIONS

The diabetic comas are often described as discrete entities, but they frequently present as overlapping disorders [2]. Patients with DKA often have concurrent mild lactic acidosis and may also develop hyperosmolality. Initial treatment of all diabetic comas must always emphasize fluid resuscitation and electrolyte repletion. DKA and HHS also require careful management of insulin therapy. Physicians must obtain the relevant history, perform a thorough physical examination, classify the disorder, and treat appropriately. The approach to treatment is summarized in Fig. 137.5. With care, nearly all patients with DKA and most with HHS can survive.

REFERENCES

Hypoglycemia occurs often in the intensive care unit (ICU) setting as both an admission diagnosis and a complication of therapy. Many factors predispose to it [1,2]. In a study of intensive insulin therapy from a surgical ICU population, hypoglycemia occurred among up to 5.1% of patients [3]. Another study of more than 2,200 ICU patients reported that nearly 7% experienced at least one episode of hypoglycemia [4]. Estimates of prevalence range as high as 25% [5]. Severe, prolonged hypoglycemia can cause permanent neurologic and cardiovascular damage [6–8]. Hypoglycemia is a consistent marker of poor outcomes including increased mortality among hospitalized patients in general [9–13], and in particular among critically ill adults [14–16] and children [17], irrespective of the presence or absence of a previous diabetes diagnosis [16].

DEFINITION OF HYPOGLYCEMIA

No specific blood glucose concentration defines hypoglycemia [7]. “Whipple’s triad” [18] defines hypoglycemia as (a) documentation of a low blood glucose concentration, (b) concurrent symptoms of hypoglycemia, and (c) resolution of symptoms after administration of glucose. Typically, this concentration in serum is <50 mg per dL (2.8 mmol). For persons with known diabetes, the American Diabetes Association advocates the definitions given in Table 138.1 [19]. The physiologic definition is a blood glucose concentration low enough to cause the release of counterregulatory hormones (e.g., catecholamines) and impair the function of the central nervous system (CNS). That blood glucose threshold can be quite variable.

Definitions of hypoglycemia in diabetes proposed by a workgroup of the American Diabetes Association and the Endocrine Society [19]. CHO, carbohydrate.
SYMPTOMS AND SIGNS OF HYPOGLYCEMIA

Counterregulatory hormones released in response to low glucose concentrations cause sympathoadrenal symptoms and signs. Prominent symptoms include hunger, tingling, shakiness, weakness, palpitations, and anxiety [20]. Corresponding signs include diaphoresis, tachycardia, peripheral vasoconstriction, and widening of the pulse pressure. These findings may be absent among patients receiving sympatholytic drugs (e.g., β-blockers) and among patients with diabetes who have autonomic neuropathy. Hypoglycemia-associated autonomic failure (HAAF) compromises awareness of, and responses to, low glucose and is a major contributor to the development of severe and recurrent hypoglycemia in patients with type 1 or advanced type 2 [21].

Early symptoms and signs of neuroglycopenia include altered vision, difficulty thinking and sensations of warmth, weakness, and fatigue. These may be followed by confusion, slurred speech, and other nonspecific behavioral changes [20]. Severe neuroglycopenia can cause disturbances of integrative function, obtundation, seizures, coma, and, rarely, a permanent vegetative state.

Hypoglycemia can be associated with acute pulmonary edema [22], supraventricular and ventricular tachycardias, atrial fibrillation, and junctional dysrhythmias [23–25]. Electrocardiographic abnormalities associated with hypoglycemia include T-wave flattening, increased Q-T interval, ST segment depression, and repolarization abnormalities [26–28]. Bradycardias have also been attributed to hypoglycemia, but only rarely [29]. Prolonged hypoglycemia can be associated with hypothermia [30–32], respiratory failure [33], hypokalemia, and hypophosphatemia [34]. Mortality rates attributable to hypoglycemia reportedly remain elevated for weeks after discharge from the ICU, but the causal relationship of that association, if any, is not understood [16].
NORMAL GLUCOSE REGULATORY PHYSIOLOGY

Glucose Utilization

Plasma glucose concentration is maintained in a narrow range (~60 to ~120 mg per dL; ~3.3 to ~6.7 mmol). The organ most dependent on glucose is the brain, which consumes ~150 g per day. Unlike fat or muscle, the CNS does not require insulin for glucose transport. During starvation, the brain uses ketone bodies as a substitute fuel (see Chapter 137 on diabetic Coma), but acquisition of the capability to use this alternate substrate requires hours to days. Even during prolonged starvation, the brain still needs ~44 g per day of glucose. Other tissues with obligate glucose needs include erythrocytes (~36 g per day) and renal medulla (~25 g per day).

Sources of Plasma Glucose

There are two sources of blood glucose: endogenously produced and ingested carbohydrate. In the postprandial state, the concentration of circulating insulin rises in response to the increase in glucose concentration and, to a lesser extent, other stimuli. Insulin promotes (a) transport of glucose into skeletal muscle for immediate use or storage as muscle glycogen and (b) hepatic storage of glucose in the form of liver glycogen. When all other metabolic demands for glucose are being met, some excess glucose is used for synthesis of triglycerides.

During brief starvation, such as when asleep, the principal source of glucose is hepatic glycogen. During prolonged starvation, glucose is derived principally from conversion of muscle-derived amino acids. Smaller contributions to gluconeogenesis are made by (a) glycerol derived from fat and (b) lactate produced by anaerobic glycolysis. When euglycemia is maintained by glycogenolysis or gluconeogenesis, insulin levels are low but never zero.

The liver stores only 60 to 80 g of glycogen, a supply that is exhausted by an overnight fast. Muscle glycogen stores are ~120 g, but this glycogen is not directly available for the maintenance of systemic glucose concentrations due to the lack of glucose-6-phosphatase in muscle. Muscle glycogen contributes to plasma glucose only via anaerobic glycolysis leading to the production of lactate, which is transported to the liver and converted into glucose. The shuttling of glucose to muscle and lactate to the liver comprises the Cori cycle. Muscle can also amidate
pyruvate to form alanine, which is then exported to the liver and converted to glucose. Gluconeogenesis occurs principally in the liver, and to a lesser extent in the renal cortex, using amino acids, glycerol, and lactate as substrates. The enzymes and pathways required for gluconeogenesis are presented in Figure 138.1.

**FIGURE 138.1** Metabolic pathways important in the response to hypoglycemia. The thick, annotated arrows indicate the key steps in glycogen breakdown and gluconeogenesis. In the presence of low circulating insulin concentrations, phosphorylase activity is increased, leading to the release of glucose-1-phosphate, which is then converted to glucose-6-phosphate and finally to glucose through the action of glucose-6-phosphatase. Glucose is also generated from three carbon precursors by gluconeogenesis. This process essentially reverses glycolysis and is controlled by four enzymes: (1) pyruvate carboxylase, (2) phosphoenolpyruvate carboxykinase, (3) fructose-1,6-diphosphatase, and (4) glucose-6-phosphatase. Within the box delimited by dotted lines, the metabolic effects of ethanol ingestion are indicated. Ethanol is converted to acetaldehyde and then to acetate, producing reduced nicotinamide adenine dinucleotide (NADH). The high concentration of NADH favors the generation of lactate from pyruvate, decreasing the concentration of the latter. As the availability of pyruvate as a gluconeogenic precursor declines, glucose production via gluconeogenesis also declines, and hypoglycemia can ensue.
Hormonal Regulation of Plasma Glucose Concentration

Insulin is the most important regulator of glycemia, promoting glucose uptake and storage in the fed state, and regulating glycogenolysis, gluconeogenesis, and lipolysis in the fasted state. Glucagon, glucocorticoids, catecholamines, growth hormone, and, to a lesser degree, thyroxine promote the formation of glucose in the fasted state and in general counteract the actions of insulin. Foremost among these “counterregulatory” hormones is glucagon, which is secreted in response to low glucose. It promotes both glycogenolysis (an immediate effect) and gluconeogenesis (a delayed but more enduring effect). Glucocorticoids antagonize the action of insulin, stimulating gluconeogenesis and inhibiting extrahepatic glucose utilization. Catecholamines also promote glycogenolysis and gluconeogenesis. The mechanism by which growth hormone promotes blood glucose elevation is not fully understood. The influence of thyroxine on blood glucose concentration is probably indirect. Fasting glucose tends to be elevated and decreased among hyperthyroid and hypothyroid patients, respectively.
CLASSIFICATION OF HYPOGLYCEMIA

Hypoglycemia can be classified as fasting (or postabsorptive) or postprandial (or “reactive”). The former always represents a major health problem that requires further evaluation. Hypoglycemia that occurs only after eating can be difficult to assess. It is usually minimally symptomatic and is attributed variously to an exaggerated insulin response, renal glycosuria, defects of glucagon responses, and/or high insulin sensitivity [35,36]. Some cases of postprandial hypoglycemia, however, are severe and associated with health issues including mutations of the insulin receptor [37], autoantibodies against insulin [38], gastric “dumping” after bypass surgery, and nesidioblastosis, all of which are described below. Postprandial hypoglycemia generally does not require intensive care.
DIFFERENTIAL DIAGNOSIS OF HYPOGLYCEMIA

Hypoglycemia that fulfills Whipple’s triad always implies a major disturbance in glucose homeostasis, which is dependent on three factors: (a) the hormonal milieu, (b) the viability of organs responsible for gluconeogenesis, and (c) availability of substrate for conversion to glucose [7]. The differential diagnosis of medically important hypoglycemia subsumes three corresponding categories: (a) states of hormonal imbalance, principally excess insulin, (b) states of impaired endogenous glucose production, and (c) states in which gluconeogenic substrates are unavailable.

Hypoglycemia due to Hormonal Imbalance

Insulin

**Insulin Overdoses in Diabetic Patients.** Insulin overdose is the most common cause of hypoglycemia. In an outpatient setting, it is frequently the result of a missed meal or increased exercise and less often the result of inadvertent injection of short-acting in place of long-acting insulin. Occasionally, an overdose is intentional, particularly among adolescents. Rarely, overdoses represent attempts at suicide and homicide [39]. The rapidity of onset [40] and duration of hypoglycemia [41] depend on the type of insulin (see Table 138.2).

Data are for recombinant human insulin or semisynthetic insulin administered subcutaneously. Protamine lispro and protamine aspart insulins are available only in fixed ratio combinations.

- **a**Semi-synthetic insulin.
- **b**Humulin is available in U100 and U500 concentrations.
- **c**Study ended at 24 hour. Trade names are given in parentheses. Additional semisynthetic insulins are under development.

Hypoglycemia is often more severe among patients with long-standing type 1 diabetes and advanced type 2 diabetes due to intercurrent HAAF [21]. This is characterized by defective counterregulatory responses and hypoglycemia unawareness. Impaired glucagon and epinephrine responses are common, resulting in the abrupt development of severe hypoglycemia [42]. When counterregulation is impaired, adrenergic warning signals like tremor, diaphoresis, and tachycardia may not occur and neuroglycopenic symptoms can develop rapidly. Inadequate counterregulatory responses can also delay recovery from hypoglycemia.

Hypoglycemia among ICU patients can result from rapid changes in clinical status, medications that impair counterregulation (e.g., high-dose $\beta$-adrenergic blockers), and the presence of intercurrent disease processes. Although insulin-induced hypoglycemia is easily diagnosed in
the ICU, it is crucial to determine exactly why it occurred. Vigilance is critical.

Intensive insulin management is demanding [43] and hypoglycemia can occur frequently [4,5]. Occasionally, insulin is administered either in the wrong dose or in response to a factitiously elevated blood glucose measurement or to the wrong patient. Even the most careful attempts to lower blood glucose in the ICU to levels <110 mg per dL, can frequently be associated with hypoglycemia [44–48]. The occurrence of hypoglycemia is more closely associated with excessive rates of insulin infusion than with the cumulative dose [49]. Failure to adjust insulin infusion rate after decreasing nutritional support is common, for example after interruption of enteral or parenteral for some reason [4]. Total parenteral nutrition solutions containing insulin can produce hypoglycemia [5], particularly if improvement in a patient’s underlying condition restores peripheral insulin sensitivity. Insulin-induced hypoglycemia in the ICU can be related to adrenal insufficiency, renal failure, sepsis, or drug toxicities, continuous venovenous hemofiltration with bicarbonate replacement fluid, and need for inotropic support [5].

**Intentional Insulin and Oral Hypoglycemic Agent Overdoses among Nondiabetic Patients.** “Factitious” hypoglycemia should be suspected for anyone with access to insulin or oral hypoglycemic agents, including health care workers and relatives of persons with diabetes. The diagnosis can be difficult. These patients are trying to frustrate rather than facilitate a diagnosis, and they may devise ingenious methods to conceal their actions. Insulin intended for surreptitious injection has been found hidden in electronic devices and body cavities. Surreptitious use of oral hypoglycemic agents, which act by increasing endogenous insulin secretion, can be particularly problematic to diagnose [50,51]. Factitious hypoglycemia can represent malingering, attempted suicide or homicide, Münchausen syndrome, and Münchausen-by-proxy syndrome [39]. It has also been reported to result from adulteration of herbal and counterfeit prescription drugs with oral agents [52,53].

**Insulinoma.** Insulinomas are insulin-secreting pancreatic islet tumors. They are uncommon but do represent the most common form of pancreatic islet neoplasm. Most (>90%) are nonmalignant. They are typically small and difficult to visualize radiographically. Endocrine Society guidelines specify the critical diagnostic findings as: plasma insulin concentrations of at least 3 μU per mL (18 pmol per L), plasma C-peptide concentrations of at least 0.6 ng per mL (0.2 nmol per L), and plasma proinsulin concentrations of at least 5.0 pmol per L when the fasting plasma glucose concentrations are below 55 mg per dL (3.0 mmol per L) [54]. For some cases, a modification of these criteria may be of use [55].
It can be difficult to differentiate among insulinoma, factitious hypoglycemia due to self-administration of insulin, and abuse of oral hypoglycemic agents. When intentional insulin overdose is suspected, insulin measurements are of limited value. Patients with factitious hypoglycemia may have circulating antiinsulin antibodies that interfere with the radioimmunoassay for insulin. This is true even when human insulin is injected. These patients may appear to have elevated levels of insulin, just as would patients with an insulinoma. In this circumstance, simultaneous glucose, insulin, and C-peptide concentrations are helpful. Insulin and C-peptide are normally co-secreted by the pancreas in equimolar quantities, but C-peptide is not present in insulin for injection. Absence of C-peptide in a patient with unexplained fasting hypoglycemia strengthens the possibility of surreptitious insulin use. If oral hypoglycemic agent abuse is suspected, both serum and urine should be screened.

Non-islet Tumors that Secrete Insulin. Rarely, complex endocrine tumors may secrete both insulin and other hormones [56–58]. Hypoglycemia due to ectopic secretion of insulin by non-endocrine tumors is rare [59–61].

Nesidioblastosis or Persistent Hyperinsulinemic Hypoglycemia (PHH). Nesidioblastosis (nonmalignant islet cell hyperplasia) is a rare form of nonmalignant islet cell adenomatosis that leads to insulin-mediated hypoglycemia. Among infants, nesidioblastosis is typically characterized by islet hyperplasia, β cell hypertrophy, and increased β cell mass. It can be either diffuse or focal and is sometimes termed PHH of infancy [62–65]. Rapid diagnosis of the childhood form is crucial to avoid hypoglycemic damage to the maturing CNS. Several different genetic mutations have been associated with the disorder cases [63,64,66–69]. Special cases of hyperinsulinemic hypoglycemia of infancy include Costello syndrome [70] and the Beckwith–Wiedemann syndrome, which is due to defects in pancreatic β cell potassium channels [71].

A few cases of adult nesidioblastosis have been reported [63,72,73]. The pathologic findings are less consistent than for infants [74], and the cause is unknown. Additional cases of PHH have been diagnosed in adults who had previously undergone Roux-en-Y gastric bypass surgery for weight reduction [75,76]. Whether these cases represent nesidioblastosis [75,77], “dumping syndrome,” or a reactive process leading to or unmasking a defect in β cell function [78] is unclear, perhaps in part because the pathologic diagnosis of nesidioblastosis is difficult [74]. The initial approach to patients with post-gastric bypass hypoglycemia should focus on avoidance of high carbohydrate content meals. Should that fail, other treatment options include diazoxide, streptozocin, calcium channel blockade [79], α-glucosidase inhibition
[79], octreotide (discussed below), percutaneous gastrostomy into the remnant stomach [80], as well as partial pancreatectomy [77].

**Antibody-Mediated (“Autoimmune”) Hypoglycemia.**
Autoimmune hypoglycemia can result from autoantibodies directed against insulin itself or autoantibodies directed against the insulin receptor [81]. Both can occur in either insulin-treated [82] or nondiabetic individuals, and both types of autoantibody can be found in the same patient [83]. About 90% of cases have been reported from Japan [84]. Serum insulin concentrations typically are extremely high, usually higher than those produced by insulinomas. It is assumed that for these cases, glucose administration causes an excessive insulin response because the antibodies buffer most of the insulin secreted [85].

Endogenous antibodies that bind to and activate the insulin receptor can also cause hypoglycemia [86]. Some, but not all, cases are associated with other autoimmune disorders [87–89], and a few have occurred among patients with myeloma [90]. Previous exposure to exogenous insulin is not necessary, but some patients may have an abnormal insulin molecule [91]. Metformin may be helpful in management [92]. Some cases respond to immunosuppressive therapy [86]. The natural history of this syndrome is that the anti-receptor antibodies disappear and the syndrome resolves over months to years [38].

**Pancreas and Islet Transplantation.** Hypoglycemia after pancreas and islet transplantation can occur [93], but it is generally not a significant clinical problem [94,95]. Islet transplantation has been reported to resolve hypoglycemia unawareness [96]. There is a report of nesidioblastosis-like transformation of a successful pancreas allograft [97].

**Non-islet Tumors with Insulin-like Activity.** Certain tumors not of pancreatic islet origin are associated with fasting hypoglycemia clinically indistinguishable from that caused by islet cell neoplasms. Whereas insulinomas are typically quite small, non-pancreatic neoplasms associated with hypoglycemia tend to be large mesenchymal tumors. The large size initially suggested that excessive glucose utilization by the tumor was the cause of the hypoglycemia, but subsequent studies suggest that most cases result from secretion of high-molecular-weight insulin-like growth factor II (pro-IGF-II or “big IGF-II”) [98–100]. Pro-IGF-II levels decrease significantly and hypoglycemia resolves after successful tumor resection [101–106]. Abnormal processing of the IGF-II molecule may play a role for some cases [102,104,107]. Non-islet cell neoplasms
associated with hypoglycemia include gastrointestinal stromal cell tumors [108], hemangiopericytoma [109–111], hepatoma [112,113], uterine tumors [114], renal tumors [115], mesenteric sarcomas [116], colorectal cancer [117], gastric cancer [118], adrenocortical carcinoma, Hodgkin’s lymphoma [119], poorly differentiated thyroid cancer [120], somatostatinoma [121], phyllodes tumor [122], and leukemia [123]. Multiple myeloma may also cause hypoglycemia via an antibody-mediated mechanism described below [89].

The diagnosis of hypoglycemia due to production of pro-IGF-II by non-islet cell tumors requires the exclusion of insulinoma. As noted above, this can be done by obtaining simultaneous insulin and glucose measurements during hypoglycemia. The observation of increased blood glucose concentration after intravenous administration of glucagon, an index of adequate glycogen stores, may also help discriminate between insulin and IGF-secreting tumors [124]. Methods have been developed for measuring serum pro-IGF-II directly [99]. Hypoglycemia associated with high levels of IGF-I has rarely been reported [125].

### Hypoglycemia due to Non-Insulin Hypoglycemic Agents

Pharmaceuticals other than insulin that are used to treat type 2 diabetes fall into two classes. “Hypoglycemic agents” enhance insulin secretion and can cause hyperinsulinemic hypoglycemia. The sulfonylureas and meglitinides belong to this class; all are taken orally. The second class is “antidiabetic agents.” These promote normoglycemia through mechanisms other than enhancement of insulin secretion; they include both oral and injectable agents. When given as monotherapy they do not cause hypoglycemia, but they can amplify the glucose-lower activity of insulin and the oral hypoglycemic agents. The thiazolidinediones (TZDs), biguanides, α-glucosidase inhibitors, SGLT-2 inhibitors, gliptins, and bromocriptine mesylate are oral antidiabetic agents. Exenatide, liraglutide, and pramlintide, among others, are injectable antidiabetic agents. As discussed below, many drugs not used for the treatment of diabetes can also amplify the glucose-lowering activity of oral hypoglycemic agents, and a complete medication history can be critical for the diagnosis of hypoglycemia.

**Sulfonylureas.** After insulin, these are the most common cause of hypoglycemia [126]. Sulfonylureas reduce serum glucose by increasing insulin secretion, which also inhibits inhibiting glycogenolysis and gluconeogenesis, enhancing the response of target tissues to the effects of insulin [127]. Three “second-generation” sulfonylureas are in use in the United States, glipizide, glyburide, and glimepiride (Table 138.3). Severe hypoglycemia is not common with appropriate administration of these drugs [128], but it can be observed in several contexts [129]. In all age
groups the condition is most often observed in the context of decreased carbohydrate intake. Maternal treatment of diabetes with glyburide can lead to postpartum hypoglycemia of their neonates [130]. Among patients between the ages of 11 and 30 years, a substantial number of hypoglycemic comas is due to sulfonylurea agents [51]. Half of these cases are suicide attempts [126]. Among patients with type 2 diabetes older than 60 years, sulfonylurea-induced hypoglycemia is a frequent complication [129,131]. Reported risk of hypoglycemia with glimepiride is 0.9% to 1.7%, with glipizide 3%, and with glyburide 21.3% [6,8]. When combined with metformin or a TZD, the risk increases 7% to 37% [6,8].

Liver disease decreases the clearance of glipizide, glyburide, and glimepiride (Table 138.3). Metabolites of sulfonylureas are excreted in urine with one exception; 50% of glyburide metabolites is excreted in the bile. Accordingly, sulfonylurea-induced hypoglycemia is often observed among older individuals in the setting of acute or chronic starvation superimposed on mild to moderate liver or renal failure. The half-life of some sulfonylureas is >24 hours and the duration of action is often even longer (Table 138.3). Hepatic and renal insufficiency can extend their half-lives. Patients with sulfonylurea-induced hypoglycemia should therefore be hospitalized after initial resuscitation with glucose. They require continued treatment with oral and intravenous glucose for a minimum of 18 to 24 hours.
When oral agent overdose is suspected, serum and urine should be screened for sulfonylurea compounds. Sulfonylurea drugs circulate bound to proteins, and drugs of several classes can displace sulfonylureas and enhance their hypoglycemic effect (Table 138.3). The constellation of insulin concentration ≥3.9 μU per mL, C-peptide ≥1.4 ng per mL, and glucose <49 mg per dL may be helpful in diagnosing sulfonylurea-induced hypoglycemia [50].

**Repaglinide and Nateglinide.** Repaglinide (Prandin) and nateglinide (Starlix), like the sulfonylureas, increase endogenous insulin secretion but do so by a different mechanism. The risk of hypoglycemia from repaglinide is 16% to 31% and from nateglinide 1.3% to 3% [6,8]. Both are rapidly eliminated. Surreptitious use of repaglinide has been reported [132].

**Antidiabetic Agents.** Biguanides, when given as monotherapy, induce hypoglycemia much less frequently than do sulfonylureas [133,134], probably by inhibiting gluconeogenesis. Metformin is the only biguanide currently available in the United States. It is also available in combination with the oral hypoglycemic agents glyburide (Glucovance), glipizide (Metaglip), and repaglinide (Prandimet); overdosage with these combination drugs can cause severe hypoglycemia. TZDs, and gliptins are also available in fixed ratio combinations with metformin; some of these have been associated with hypoglycemia.

Drugs of the TZD class, including pioglitazone (Actos) and rosiglitazone (Avandia), do not cause hypoglycemia when used as monotherapy but can potentiate hypoglycemia caused by insulin or sulfonylureas. They act by increasing insulin sensitivity.

Acarbose (Precose) and miglitol (Glyset) are α-glucosidase inhibitors that inhibit the digestion of complex carbohydrates; they have not been reported to cause hypoglycemia when used as monotherapy. Patients treated with insulin or sulfonylureas in addition to acarbose who experience hypoglycemia may not respond to the oral administration of complex sugars, but should respond to monomeric glucose.

Exenatide (Byetta), dulaglutide (Trulicity), albiglutide (Tanzeum), lixisenatide (Lyxumia), and liraglutide (Victoza) are injectable mimetics of gut incretins [135,136]. They augment glucose-dependent insulin secretion and reduce postprandial glucagon secretion. When given as monotherapy they rarely cause hypoglycemia but the risk increases with concurrent sulfonylurea use.

Gliptins are inhibitors of the enzyme dipeptidyl peptidase-4. They inhibit the degradation of endogenous gut incretins and have glucose-lowering effects and hypoglycemia risks similar to those of the gut incretins. Drugs in this class include sitagliptin (Januvia), linagliptin (Tradjenta), alogliptin (Nesina), and saxagliptin (Onglyza).
Pramlintide (Symlin) is a mimetic of the islet hormone amylin [136]. It suppresses post-meal glucagon secretion and delays gastric emptying. It is targeted at controlling post-meal hyperglycemia in diabetic patients who are also taking insulin. Like exenatide, it has been associated with hypoglycemia.

Gliflozins are inhibitors of the sodium-glucose transport protein 2 (SGLT2) in the kidney. They reduce blood glucose by reducing reabsorption of glucose by the kidney and as monotherapy do not cause hypoglycemia [6]. Available SGLT2 inhibitors include canagliflozin (Invokana), empagliflozin (Jardiance) and dapagliflozin (Farxiga). All are available in combination with metformin or a gliptin and these combination products can sometimes cause hypoglycemia.

Bromocriptine is an oral dopamine agonist that is used in the treatment of pituitary tumors and Parkinson’s disease. A micronized formulation (Cycloset) is approved for treating type 2 diabetes [137]. Its mechanism of action is unclear. It has not been reported to cause hypoglycemia, but experience with the drug is limited.

**Medication Errors.** Severe hypoglycemia can result from inadvertent substitution of an oral hypoglycemic agent for a different medication. Medication errors due to phonetic similarity in name are exemplified by cases in which chlorpropamide or chloroquine has been prescribed but chlorpropamine (an older sulfonylurea) inadvertently dispensed [126,138].

**Other Drugs and Poisons that Cause Hypoglycemia**

Hundreds of drugs and toxins have been reported to cause or predispose to hypoglycemia (Table 138.4). For some, like ethanol, the association is well documented and the mechanism well understood. For most, however, the evidence supporting an association is poor and the mechanism of action is unknown. Some are based only on a single case report. In some instances, drug–drug interactions may be amplifying the hypoglycemic effect of concurrently administered oral hypoglycemic agents. In other instances, the data are contaminated by intercurrent sepsis or other disease. Few re-challenge data to support the association are available. An analysis of the quality of the evidence implicating many drugs as the cause hypoglycemia is available [139] as is a review of mechanisms and relative risk [8]. Some drugs with stronger supporting evidence are indicated in Table 138.4.

Data for some listed agents are very limited or anecdotal or involved treatment with more than one drug. Drugs for which better documentation is available are indicated in bold italic. MDMA: 3,4-methylenedioxyamphetamine.

ACE, angiotensin-converting enzyme.
Ethanol-Induced Hypoglycemia (Alcoholic Ketoacidosis)

Ethanol-induced hypoglycemia is most often observed among children and chronic alcohol abusers. The most common history is binge drinking in the setting of poor intake of other dietary carbohydrates. Patients usually present in a stuporous or comatose state; nausea, vomiting, and abdominal pain are common. Ethanol concentration is typically low, and alcoholic hypoglycemia can occur up to 30 hours after the ingestion of alcoholic beverages. Blood glucose as low as 5 mg per dL has been recorded. Ketonuria and ketonemia are frequently present and reflect the appropriately low circulating insulin concentration [140].

Ethanol causes hypoglycemia by suppressing hepatic gluconeogenesis. Glycogenolysis is not affected. When ethanol is oxidized to acetaldehyde and acetate, NAD$^+$ is reduced to nicotinamide adenine dinucleotide (NADH). The reduced NAD$^+$:NADH ratio produces an unfavorable intracellular environment for the oxidation of substrates of gluconeogenesis such as lactate and glutamate to pyruvate and α-ketoglutarate, respectively (Fig. 138.1). As a result, intracellular levels of pyruvate are below the Michaelis constant ($K_m$) of pyruvate carboxylase, one of the rate-limiting steps for gluconeogenesis. Ethanol also inhibits hepatic uptake of the gluconeogenic precursors glycerol, alanine, and lactate, and inhibits the release of alanine from muscle [141].

Management consists of rehydration with intravenous fluids and glucose to correct hypoglycemia. Parenteral thiamine (100 mg) should be given to prevent Wernicke’s encephalopathy. Treatment with glucose and fluids rapidly reverses the condition and sodium bicarbonate is generally unnecessary.

β-Adrenergic Receptor Antagonists

The nonselective β-blockers propranolol, pindolol, and nadolol reportedly predispose to hypoglycemia in diverse clinical settings, often by synergizing with another agent or delaying recovery. Both diabetic and nondiabetic patients undergoing hemodialysis are susceptible. Neonates may also have hypoglycemia during their first 24 hours of life as a result of propranolol treatment of the mother for cardiac arrhythmias, hypertension, or thyrotoxicosis. Hypoglycemia of infants treated with propranolol for congenital hemangiomas, cyanotic heart disease, and neonatal thyrotoxicosis has also been reported. Hypoglycemia is a documented complication of β blockade among pediatric ICU patients [142]. These drugs increase the risk of hypoglycemia among patients who are undernourished or who have liver disease [141] and occasionally
when administered prior to cardiac surgery [126,143].

Antiarrhythmic Agents

Quinidine can enhance insulin secretion and produce hypoglycemia in ill, fasting patients [144]. Hypoglycemia has been reported in patients treated with diisopyramide, an antiarrhythmic agent with pharmacologic properties similar to those of quinidine [145,146]. In neither case is supporting evidence strong. The investigational antiarrhythmic cibenzoline is more convincingly associated with hypoglycemia [147].

Antibiotics

There is evidence [139] that pentamidine, used to treat Pneumocystis jiroveci infection, can be toxic to pancreatic β cells, causing transient hypoglycemia due to the release of stored insulin. It eventually results in diabetes in some patients [126]. Similarly, quinine, chemically related to quinidine, is known to elevate insulin concentrations of patients being treated for malaria [148,149]. Those with cerebral malaria are most prone to hypoglycemia, possibly due to the high intake of glucose by malarial parasites, coupled with the increased insulin release. Quinine may rarely cause hypoglycemia among normal individuals [150].

Gatifloxacin (Tequin) [151–154], levofloxacin (Levaquin) [151,155], ciprofloxacin (Cipro) [156,157], and other fluoroquinolones reportedly cause hypoglycemia, particularly when administered to patients who are also receiving sulfonylureas. Gatifloxacin may carry the highest risk of hypoglycemia, yet paradoxically some patients treated with this drug also experience new-onset hyperglycemia [151]. Trimethoprim/sulfamethoxazole has also been reported to cause hyperinsulinemic hypoglycemia in the setting of malnutrition and infection, renal failure [158], and oral hypoglycemic therapy [159].

Salicylates

Salicylate intoxication reportedly causes hypoglycemia occasionally among children but only very rarely in adults [126,160]. Among children, it may be a component of aspirin-associated Reyes syndrome [161]. The frequency of salicylate-induced hypoglycemia is difficult to ascertain due to intercurrent acidosis and renal or hepatic impairment for many cases of intoxication.
Angiotensin-Converting Enzyme Inhibitors

Cases of hypoglycemia associated with angiotensin-converting enzyme (ACE) inhibitors have been reported among persons with both types 1 and 2 diabetes [162–165], but the quality of the evidence is low [139]. No mechanism for the effect has been identified, and a retrospective analysis of nearly 14,000 persons with diabetes failed to identify an increased risk of hypoglycemia associated with this class of drugs [166].

Poisons

Several plant substances can cause hypoglycemia. Hypoglycin A toxin is found in akee fruit, a staple of the Jamaican diet. The ripe fruit is edible, but immature fruit causes vomiting a few days after ingestion. Affected patients have severe hypoglycemia due to inhibition of hepatic gluconeogenesis by hypoglycin [167]. Amanita toxins produced by the mushroom *Amanita phalloides* are inhibitors of RNA polymerase and cause hepatocellular necrosis. Fatal hypoglycemia can result from the ensuing complete depletion of hepatic glycogen and decreased capacity for gluconeogenesis [141].

Hypoglycemia Associated with Deficiencies of Counterregulatory Hormones

Glucocorticoid insufficiency can cause hypoglycemia among children by decreasing glycogenolysis and gluconeogenesis. In adults, it causes hypoglycemia uncommonly [168]. Malnutrition may contribute to the development of hypoglycemia in these cases. Patients with panhypopituitarism are prone to hypoglycemia and have increased sensitivity to insulin [168]. Although catecholamines play a significant role in preventing and reversing hypoglycemia, their absence does not commonly predispose to hypoglycemia. Adrenalectomized patients with sympathetic denervation due to spinal cord transection maintain euglycemia. Glucagon deficiency, as in persons with post-pancreatectomy diabetes, can contribute to hypoglycemia.

Fasting Hypoglycemia due to Inadequate Production of Endogenous Glucose
Liver Damage

About 90% of gluconeogenesis occurs in the liver, and the remainder in the renal cortex. Hepatic injury can cause hypoglycemia but only when the insult is very severe; only about 20% of normal liver biosynthetic capability is needed to maintain normal glucose homeostasis [169]. Hypoglycemia seldom occurs in the setting of isolated, limited hepatic failure and is not the cause of hepatic coma [141]. Hypoglycemia due to toxic or infectious hepatitis is rare but does occur when the disorder is fulminant. Hepatotoxins that can impair gluconeogenesis and cause hypoglycemia include carbon tetrachloride, the A. phalloides mushroom toxin, and urethane. Drugs that cause hypoglycemia by inducing hepatocellular necrosis include acetaminophen, isoniazid, sodium valproate, methyldopa, tetracycline, and halothane [141]. Neither tests of hepatocellular integrity (e.g., transaminases) nor tests of hepatic function (e.g., bilirubin concentration) nor the presence of structural damage (e.g., cirrhosis, chronic active hepatitis, metastatic liver disease) correlate well with the capability of the liver to maintain normoglycemia.

Congestive heart failure (CHF) from any cause can lead to hepatic congestion and hypoglycemia among adults and children. Patients with this syndrome usually have severe failure with cardiac cachexia, malnutrition, and muscle wasting. The mechanism by which CHF leads to hypoglycemia is not completely understood. Changes in hepatic blood flow may alter the delivery of gluconeogenic precursors or changes in intracellular redox state may decrease the gluconeogenic capacity of the hepatocyte. Hypoglycemia in this setting resolves with successful treatment of the CHF [141]. Hypoglycemia in association with CHF due to thyrotoxicosis [170] and rewarming from severe hypothermia [171] have been reported.

Renal Damage

Some patients with diabetes develop improved glucose tolerance with the onset of renal failure. A decrease in insulin requirements and more frequent episodes of hypoglycemia may also occur [172]. There is no correlation between degree of renal failure and severity of hypoglycemia for these patients, and the underlying mechanisms are not completely understood. Investigators variously implicate delayed insulin clearance, deficiencies of the delivery of gluconeogenic substrate [168], and hepatic insufficiency secondary to uremia [173].

Symptomatic hypoglycemia occurs among many diabetic patients receiving either hemodialysis or ambulatory peritoneal dialysis [174,175]. Any dialysis patient who experiences a change in mental status should be evaluated for hypoglycemia. The symptoms and signs of neuroglycopenia
resemble those of the dialysis disequilibrium syndrome commonly induced by fluid shifts. These include fatigue, confusion, lethargy, and even coma. Post-dialysis hypoglycemia in diabetic patients, if prolonged, can be fatal [176].

Spontaneous fasting hypoglycemia has also been reported to occur among nondiabetic patients with end-stage renal disease [177–179]. It is not clear, however, whether these rare cases represent a distinct clinical entity [180] or instances of renal failure enhancing intercurrent disorders that predispose to hypoglycemia [181]. These might include drug ingestion, liver disease, and adrenal or pituitary insufficiency.

**Fasting Hypoglycemia due to the Unavailability of Gluconeogenic Substrate**

Substrate deficiency leads to hypoglycemia in ketotic hypoglycemia of childhood [182]. Patients with this condition, a variant of the normal response to starvation, are usually diagnosed between 18 months and 5 years of age. The hallmark of the condition is a low basal concentration of the gluconeogenic precursor alanine, and the hypoglycemia can be corrected with either glucose or alanine.

**Other Causes of Hypoglycemia**

**Sepsis**

Sepsis has occasionally been implicated as a cause of hypoglycemia [183–186]. Shock and liver failure were intercurrent problems in some cases [184]. Under conditions of decreased hepatic reserve, the combination of circulatory failure and impairment of gluconeogenesis by endotoxin may lead to hypoglycemia. Septic hypoglycemic patients are often acidotic, and the fatality rate is high [183,184]. In one report, only 1 of 15 such patients survived 1 month after onset of hypoglycemia and hypotension [184].

**Congenital Disorders**

The most common cause of neonatal hypoglycemia is maternal diabetes [187]. Congenital enzyme deficiencies and other abnormalities of the function of specific enzymes typically produce hypoglycemia in the context of glycogen storage disease, impaired hepatic gluconeogenesis, or respiratory chain defects [188]. Mutations of the sulfonylurea receptor can also cause this disorder [67]. These uncommon conditions usually present as hypoglycemia during infancy, but they can rarely present as
unexplained persistent hypoglycemia of a critically ill adult \([83,189]\). The pediatric disorders are reviewed elsewhere \([64,65,190]\).

**Exercise-Induced Hypoglycemia**

Exercise-induced hyperinsulinemic hypoglycemia is an autosomal-dominant hyperinsulinemia syndrome \([191]\). The cause appears to be to failure of \(\beta\) cell–specific transcriptional silencing of a gene, monocarboxylate transporter 1, important for pyruvate-stimulated insulin release \([192]\).
LABORATORY DIAGNOSIS OF HYPOGLYCEMIA

Normal Blood Glucose Concentration

Normal plasma glucose is 60 to 120 mg per dL (3.3 to 6.7 mmol). Whole blood glucose concentrations are 15% to 20% lower. Fingerstick blood glucose determinations are performed on whole capillary blood, and most meters reflect this offset. Symptoms of hypoglycemia generally occur when plasma glucose is <50 mg per dL (2.8 mmol) or the whole blood glucose concentration is <40 mg per dL (2.2 mmol), but for any given individual (especially in individuals with long-standing hyperglycemia), it may occur at higher glucose concentrations (Table 138.1). Calibrated hospital-quality glucose meter technology is accurate over a wide range of concentrations; values between 40 and 350 mg per dL generally agree well with values obtained using standard laboratory methods. Glucose meters for home use can be less accurate [193]. Because fingerstick blood glucose determinations can be less accurate at the lower end of their scale, they may require confirmation by a clinical laboratory.

Interpretation of fingerstick glucose should take into account the clinical context, symptoms, and response to glucose administration. Fingerstick glucose can be particularly misleading among patients who are hypoperfused [194,195], in shock [196], or undergoing cardiopulmonary resuscitation [197]. Certain meter technologies are inaccurate in the presence of various interfering substances [198,199]. Newer point of care glucose meters that are FDA approved for use in critically ill patients are recommended over older ones for use in the ICU [200]. Nevertheless, in patients who are hypoperfused or with anasarca, the accuracy of fingerstick glucose values should be confirmed by whole blood glucose values before relying on fingerstick obtained specimens.

There are several physiologic exceptions to guideline values for diagnosing hypoglycemia in very ill patients. After about 48 hours of starvation, many individuals, particularly women, have a plasma glucose concentration less than 50 mg per dL (2.8 mmol). After 72 hours of fasting, the plasma glucose may approach 40 mg per dL (2.2 mmol). Starved individuals are nonetheless asymptomatic, do not fulfill Whipple’s triad, and are not physiologically or clinically hypoglycemic. The absence of symptoms is due to the shift to ketones for CNS metabolism. Comparably low plasma glucose, 60 mg per dL (3.3 mmol) or less, can also be encountered during pregnancy. Again, there are no symptoms of hypoglycemia per se in these cases. Finally, rare individuals
may have an anomalously low “set point” for blood glucose concentration, and such individuals appear asymptomatic in the face of persistent glycemia in the range of 35 to 45 mg per dL [201].

**Spurious Hypoglycemia**

This term applies to glucose concentrations that are reported to be low but come from a normoglycemic patient. This most commonly occurs as a result of storing blood samples at room temperature for long periods before laboratory analysis. As a result of anaerobic glycolysis by blood elements, the actual glucose concentration in the test tube may decline. The effect is enhanced if large numbers of white blood cells are present in the sample as the result of severe leukocytosis or leukemia [202]. Perhaps surprisingly, even a laboratory glucose determination can be spurious because plasma glucose concentration remains difficult to assay with consistent accuracy [203].

**Spurious Hyperglycemia Leading to Insulin Overdose**

Falsely elevated glucose readings can lead to inappropriate insulin administration and hypoglycemia. The commonest cause of spurious hyperglycemia in the ICU is measurement of glucose of blood obtained from an extremity into which glucose is being infused. An uncommon cause of hypoglycemia in the ICU results from a “drug–device interaction” affecting patients receiving parenteral nutrition products containing maltose or galactose. These products cause certain monitoring systems to give falsely elevated glucose readings leading to inappropriate insulin treatment [198].

**Testing for Ketonuria**

Urinary ketone testing can facilitate the differential diagnosis of hypoglycemia. Normally, fasting is associated with low circulating insulin that promotes gluconeogenesis and lipolysis. Hypoglycemia in association with ketonuria enhances the likelihood that the cause is not excess insulin.

**Other Studies**

In addition to glucose and urinary ketones, additional tests should be ordered as appropriate to the patient’s underlying medical condition. In general, these should always include studies of hepatic and renal function. Obtain additional serum and plasma samples from any comatose, hypoglycemic patient when they are first seen. This permits
assays for medications, insulin/glucose ratios, proinsulin, and C-peptide to be performed later, if indicated. Testing for oral hypoglycemic agents requires sophisticated laboratory methods, and it is recommended that laboratory personnel be consulted to insure that appropriate specimens (urine, blood, or both) are ordered. A cosyntropin (Cortrosyn) test should be performed when adrenal insufficiency is suspected.
MANAGEMENT OF HYPOGLYCEMIA

Initial Management with Glucose

When symptomatic hypoglycemia is suspected, remember Whipple’s triad. After fingerstick glucose determination, the treatment is glucose administration, and the diagnostic outcome is resolution of symptoms. It is important to document the presence of hypoglycemia before giving glucose. Most patients with depressed mental status are not hypoglycemic [204].

The practice of giving intravenous glucose empirically assumes that it could be useful and is always harmless [205]. This belief has been called into question. In cases of stroke, in particular ischemic stroke, hyperglycemia may be predictive of poor outcome [206,207], and empiric use of hypertonic dextrose has been discouraged by many authors [197,204,208,209]. In addition, even for those cases in which empiric glucose appears to be resuscitative, there is no way to back-calculate what might have been the antecedent glucose concentration [210]. In the hospital, treatment of hypoglycemia is with intravenous D-glucose (dextrose) if a patient is unresponsive or might aspirate, but if a patient is alert and cooperative, oral carbohydrate (e.g., sucrose in orange juice or glucose tablets or gel) is preferable.

In general, all comatose patients, including trauma patients, should undergo fingerstick glucose determination, and the threshold for administration of intravenous glucose in addition to standard life-support measures should be low. Treatment with glucose is lifesaving in the presence of hypoglycemic coma. Early responders recognize that altered mental status due to hypoglycemia is sometimes the root cause of an accident [211].

The initial treatment of hypoglycemia for the patient with stupor or coma has traditionally consisted of the intravenous injection of 50 mL of 50% dextrose in water (D$_{50}$W) over 3 to 5 minutes. Care must be taken to avoid subcutaneous extravasation; the solution is hypertonic and can cause local tissue damage and severe pain. Alternatively, 10% dextrose delivered in 5 g (50 mL) aliquots can be equally efficacious and results in lower posttreatment blood glucose levels [212]. If hypoglycemia is present, treatment with glucose usually leads to improved mental status within minutes. It is difficult, however, to predict the magnitude of the glucose response to a bolus of intravenous glucose [209], and elderly patients and patients with very prolonged hypoglycemia may have a delayed response.
Subsequent Management

Glucose

The prompt improvement that usually occurs in hypoglycemic patients treated with intravenous glucose can be misleading. When hypoglycemia occurs in a diabetic patient taking insulin, no additional treatment may be needed, but there are many other causes of hypoglycemia. The initial bolus of glucose treats the symptoms of hypoglycemia but not their cause. The most common error of the management of hypoglycemia is inadequate treatment leading to recurrent symptoms.

After the first bolus of $D_{50}$W, an infusion of $D_5$W or $D_{10}$W glucose should be started in any patient whose hypoglycemic episode is not clearly due simply to excess short- or intermediate-acting insulin. The choice of $D_5$W or $D_{10}$W glucose depends on the severity of the initial hypoglycemia. This infusion allows the critical care physician to evaluate the cause of the hypoglycemic episode while protecting the patient from recurrence. An appropriate target glucose concentration is 100 mg per dL (5.6 mmol). It is advisable not to overtreat with glucose, especially for oral hypoglycemic agent poisoning. Extremely high serum glucose may stimulate endogenous insulin secretion, causing rebound hyperinsulinemia and recurrent hypoglycemia [213].

Hypoglycemia due to Long-Acting Insulin

When a long-acting insulin (Table 138.2) might have caused the hypoglycemic episode, continuation of the glucose infusion, fingerstick blood glucose testing, and periodic adjustment of the infusion rate may be required. The duration of therapy depends on the particular insulin preparation and the dose taken. Massive insulin overdose (2,500 units of NPH) has been associated with persistent hypoglycemia for up to 6 days [211].

Hypoglycemia due to Sulfonylureas

When the cause of hypoglycemia is sulfonylurea ingestion (Table 138.3), the patient should usually be admitted to hospital because of the prolonged duration of action of most members of this class of drugs. Efforts to prevent drug absorption and increase elimination should be considered. Activated charcoal adsorbs sulfonylureas, and urinary
alkalinization may enhance excretion [214,215]. Charcoal hemoperfusion is probably not indicated except in the setting of renal failure and massive overdose [216]. Continuous intravenous glucose is mandatory. Oral carbohydrate should be provided when the patient can eat. It is particularly important that the glucose infusion be continued while the patient recovering from a sulfonylurea overdose is asleep. Cases of persistent sulfonylurea-induced hypoglycemia requiring up to 27 days of intravenous glucose have been reported [217]. The typical patient with this condition requires 2 to 3 days of intravenous glucose therapy [126,218]. As discussed below, octreotide and diazoxide may be helpful adjuvant therapies for some cases.

**Refractory Hypoglycemia**

If the history and physical examination do not immediately establish the underlying cause of hypoglycemia, continuation of the infusion and glycemia monitoring are required. Persistent severe hypoglycemia requires intensive monitoring. Blood glucose should be measured every 1 to 3 hours and the serum glucose concentration maintained at a target level of 100 mg per dL (5.6 mmol per L). Diagnostic studies can be obtained as appropriate during continuous glucose infusion.

Intravenous glucose should continue until normoglycemia is achieved. To determine whether parenteral glucose is no longer needed, the infusion should be discontinued and blood glucose concentration measured every 15 minutes. If blood glucose falls to <50 mg per dL or if the patient becomes symptomatic, glucose infusion is resumed.

Depending on the etiology of the hypoglycemia, parenteral glucose infusion may be required for many days and the use of additional drugs should be considered (see below). When hypoglycemia is due to impaired gluconeogenesis in the setting of liver disease, renal disease, or CHF, only treatment of the underlying condition will prevent recurrence. When a tumor is the course of hypoglycemia, surgery is the definitive therapy.

**Drugs Other than Glucose for the Management of Hypoglycemia**

Most cases of hypoglycemia in the ICU can be treated with glucose alone. When recurrent severe hypoglycemia or volume management are problems, intensivists may wish to consider the addition of adjunctive therapies. Particularly when hypoglycemia is due to an insulinoma, nesidioblastosis, or other tumor, it may be necessary to supplement the glucose infusion with drugs that inhibit insulin secretion.
Glucocorticoids

Parenteral adrenocortical steroids can increase gluconeogenic substrates and inhibit insulin action in the periphery. Hydrocortisone sodium succinate can be given at a dose of 100 mg per L of glucose infused. This therapy is beneficial for patients whose hypoglycemia is in the context of adrenocortical insufficiency; one case report describes utility for hemangiopericytoma-associated hypoglycemia [110]. It is not helpful for sulfonylurea poisoning [219].

Octreotide (Sandostatin)

Somatostatin is produced in pancreatic islet delta cells and inhibits insulin secretion. The long-acting analog octreotide can inhibit sulfonylurea-induced insulin secretion, and it has been used as supplemental therapy for insulinomas [220], oral agent-induced hypoglycemia [221–228], quinine-induced hypoglycemia in with the treatment of malaria [149], and reportedly in insulin glargine overdose where the mechanism of action is obscure [229]. The dose is 1 to 2 units per kg every 8 hours [224].

Diazoxide (Hyperstat)

Diazoxide is a benzothiadiazine non-diuretic antihypertensive agent that blocks the secretion of insulin from both normal and neoplastic \( \beta \) cells. To treat hypoglycemia, diazoxide is infused at a dose of 300 mg (1 to 3 mg per kg in children) in D\(_5\)W over 30 minutes every 4 hours, or as a constant infusion of 1 mg/kg/h. It has been reported to be effective in reversing severe, refractory hypoglycemia due to sulfonylurea poisoning [219], noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS) [230], and neonatal hyperinsulinemic hypoglycemia due to certain gene mutations [231].

Glucagon

The primary action of exogenous glucagon in the treatment of hypoglycemia is the promotion of glycogenolysis. It is most effective in patients with ample liver glycogen stores. Glucagon is a useful drug for out-of-hospital treatment of hypoglycemia due to excess insulin of known diabetic patients. It is good practice to teach family members of diabetic
patients to administer parenteral glucagon. In the intensive care setting, however, there is seldom need to administer glucagon unless vascular access cannot be maintained. In addition, glucagon can stimulate insulin secretion and promote recurrent hypoglycemia [232]. It has also been associated with hypoglycemia when used as premedication for endoscopy [233].

**Rapamycin (Sirolimus)**

In one case report, rapamycin was effective in controlling intractable hypoglycemia in a patient with metastatic insulinoma [234]. The drug was thought to act both by reducing the malignant β cell proliferation and by inhibiting insulin production. In another case report it was used to treat hyperinsulinemic hypoglycemia of infancy [235].
PREVENTION OF HYPOGLYCEMIA IN THE ICU

With reported prevalence rates of 5% and higher [3–5], prevention of hypoglycemia is central to the metabolic management of the ICU patient. In general, oral antidiabetic agents like sulfonylureas should be discontinued for seriously ill patients [236]. Insulin infusions require meticulous management. Several studies have demonstrated that hypoglycemia can be avoided while achieving glycemic control by using structured insulin orders and management algorithms [237,238]. Such protocols are discussed in detail in Chapter 136. Up to a third of patients admitted to an emergency department with severe hypoglycemia may experience recurrent hypoglycemia in the hospital [239]. Strategies for preventing recurrent hypoglycemia have been outlined above.

Finally, it is becoming clear that promising new technology for continuous monitoring of glucose concentration has the potential to prevent hypoglycemia in the ICU [240]. Initial reports suggest that this technology enhances the detection of hypoglycemia in neonates [241] and reduces the frequency of hypoglycemic events in the adult ICU [242–244], though newer studies have not confirmed this [245]. It may not be useful in certain circumstances [245]. How this technology will affect glycemic control [242] or the management of neonatal hypoglycemia [241] or ICU outcomes remains to be determined but is potentially transformative, especially as closed-loop artificial pancreas systems are perfected [246].
CONCLUSIONS

Hypoglycemia is a serious problem for any hospitalized patient and a predictor of mortality for the critically ill [14,15]. It must be considered for all cases of stupor and coma. Diagnosis is based on Whipple’s triad, and evaluation should take no more than a few minutes. After initial therapy with glucose, remember that only the symptoms and not the cause have been treated. The most common cause of hypoglycemia is insulin overdosage among individuals with diabetes; in the ICU this can be a complication of strict glucose control protocols. Hypoglycemia due to intercurrent medical conditions requires correction of the underlying disorder. Patients with sulfonlurea- or insulinoma-induced hypoglycemia may require aggressive treatment of hypoglycemia with parenteral glucose for many days. Key points are summarized in Table 138.5.

Key elements in the diagnosis and management of hypoglycemia in the ICU.
ICU, intensive care unit; CPR, cardiopulmonary resuscitation.

20. Hillson RM: Hypoglycemia and hypothermia. Diabetes Care 6(2):211,
1983.

1. Adams J, Lodge JPA, Parker D: Liver transplantation for metastatic

1972.

Montgomery H, Myerson S: 3,4-methylenedioxymethamphetamine

The adrenal glands secrete five types of hormones, but two are critical in the intensive care unit (ICU) setting. Mineralocorticoids (primarily aldosterone) regulate electrolyte balance. Glucocorticoids (primarily cortisol) promote gluconeogenesis and have many other actions. Aldosterone and cortisol are life sustaining; deficiency of either can result in hypoadrenal crisis. The other three adrenal hormones (dehydroepiandrosterone and its sulfate, estrone, and catecholamines) do not play a major role in the acute care settings.

Hypoadrenal crisis can occur as an acute event in individuals lacking a prior history of adrenal disorders. A high index of suspicion arises for patients who have inadequate responses to initial therapies. Patients treated with glucocorticoids have a heightened risk for inadequate cortisol response to stress. Diagnosis of cortisol deficiency can be elusive; conditions that contribute to ICU admission (e.g., sepsis and acute respiratory failure) might interfere with traditional tests of adrenal function.

The uncertainty of biochemical diagnosis of adrenal hypofunction invokes the use of clinical judgment for starting therapy. Recent studies indicate that varied diseases among ICU patients do not allow a unified algorithm for treatment. Because excess glucocorticoids are beset with side effects and exacerbation of illness, it is prudent to use them only when clinically necessary.
ETIOLOGY

The most common cause of primary adrenal failure is Addison’s disease, an autoimmune disease that is frequently known before ICU admission. Addison’s disease often coexists with other autoimmune endocrinopathies, such as Hashimoto thyroiditis. Other causes of adrenal insufficiency present a difficult diagnosis in the ICU: overwhelming sepsis, hemorrhage secondary to trauma, circulating anticoagulants or anticoagulant therapy, tuberculosis, fungal diseases, amyloidosis, acquired immune deficiency syndrome, antiphospholipid syndrome, adrenal infarction, irradiation, metastatic disease, and drugs [1–3]. Therefore, critical illness can cause or unmask adrenal insufficiency. Waterhouse-Frideichson syndrome is one of adrenal hemorrhage and is associated with meningococcemia. Petechiae have been reported in 50% of patients. There have been other infectious etiologies that have been associated with adrenal hemorrhage and sepsis as well.

The most common cause of secondary adrenal insufficiency is suppression of corticotrophin (adrenocorticotropic hormone [ACTH]) release by prior glucocorticoid therapy. ACTH regulates the maintenance of cells in the zona fasciculata and the synthesis and release of cortisol from these cells. Glucocorticoid therapy suppresses ACTH, thereby causing involution of the cortisol-producing cells. The anterior pituitary regains its ability to respond to stress before normal adrenal function is restored. There are no cut-offs on duration of glucocorticoid therapy, its route of administration, and its dosage that can cause adrenal cortical atrophy (zona fasciculata) and inadequate cortisol reserve. Adrenal suppression may even occur in patients without obvious clinical signs of Cushing syndrome. Symptoms of withdrawal mimic those of Addison disease, such as weakness, lethargy, abdominal discomfort, arthralgias, myalgias, and weight loss. After short-term glucocorticoid treatment, symptoms may arise despite an intact hypothalamic–pituitary–adrenal axis by standard tests of adrenal reserve. These findings underscore the widespread and differential action of glucocorticoids among individual patients.

Pituitary dysfunction can also result in cortisol but not aldosterone insufficiency. Noteworthy causes of impaired pituitary function are tumors in the region of the sella turcica and irradiation of the pituitary or hypothalamus. Pituitary apoplexy is a rare cause of adrenal crisis. Patients usually have sudden symptoms due to cortisol deficiency such as shock. Patients with infarction of a large tumor usually have a severe headache and may have acute visual loss or decrease in visual fields.

Actions of Aldosterone and Cortisol
The adrenal cortex secretes aldosterone from the zona glomerulosa and cortisol from the zona fasciculata. Aldosterone promotes the reabsorption of sodium and the secretion of potassium and hydrogen in the renal tubule [4]. This mineralocorticoid is controlled mainly by the renin–angiotensin system; regulation of blood pressure is coordinated in the short term (angiotensin action on a membrane-bound receptor) and in the longer term (aldosterone, nuclear action on gene expression). Glucocorticoid suppression of ACTH, or primary ACTH loss, does not suppress aldosterone in the zona glomerulosa. Glucocorticoids promote gluconeogenesis and protein wasting and increase the secretion of free water by the kidney [5]. In large doses, cortisol binds to aldosterone receptors in the kidney, thereby increasing sodium reabsorption and potassium and hydrogen ion excretion. Glucocorticoids act on numerous tissues, including the central nervous system, and affect the sense of well-being, appetite, and mood. They inhibit ACTH release through hypothalamic and pituitary actions. Glucocorticoids have direct effects on the cardiovascular system and maintain blood pressure, although mechanisms are not established.

Excess glucocorticoid therapy causes lymphopenia, leukocytosis, and eosinopenia [6]. It can lead to osteoporosis and reduction of hypercalcemia [7] and can impair host defenses to infectious diseases. These possible adverse effects should be considered in the decision to treat ICU patients with glucocorticoids.

Aldosterone deficiency results in sodium wasting, with concomitant loss of water and an increase in renal reabsorption of potassium. A decrease in plasma volume and dehydration occurs, with subsequent increases in blood urea nitrogen and plasma renin activity.

Reduction of circulating cortisol levels causes a marked increase in circulating levels of ACTH and a corresponding increase in β-lipotropin, from which melanocyte-stimulating hormone activity increases. In longstanding primary adrenal insufficiency, the skin (especially creases and scars) develops hyperpigmentation [8]. Orthostatic hypotension can progress to frank shock in a crisis. Hypoglycemia and an increase in sensitivity to insulin are commonplace. Hyponatremia is a hallmark of aldosterone deficiency, but may also be found in cortisol deficiency. The mechanism for the latter may invoke increased sensitivity to vasopressin [9]; serum potassium levels would be normal.
Clinical manifestations that suggest adrenal insufficiency include a nonspecific history of progressive weakness, lassitude, fatigue, anorexia, vomiting, and constipation. A patient in adrenal crisis is volume depleted and hypotensive or in frank shock [10,11]. He or she often has a fever or is in a stupor or coma. In a precipitous event (adrenal hemorrhage, overwhelming infection, anticoagulant therapy, trauma, and surgery), adrenal crisis lacks hyperpigmentation. In one study, flank pain was observed in 86% of patients who had adrenal hemorrhage or infection as the cause of their adrenal insufficiency. Nausea was also reported in the same case report of 20 patients to be present in 47% of patients.

Severely ill patients are often suspected of developing absolute adrenal hypofunction, but actual incidence is about 3%. To further complicate recognition of adrenal dysfunction, glucocorticoid resistance has been postulated in critical illness.

Among critically ill patients, the diagnosis of adrenal hypofunction is less apparent than it is for ambulatory outpatients. Severe illness can interfere with the adrenal response to ACTH, making difficult interpretation of cortisol reserve and adrenal function. Lack of ACTH shares symptoms of primary glucocorticoid deficiency, in particular hypoglycemia. ACTH deficiency due to pituitary disease generally occurs after deficiency of other pituitary hormones; deficits of overall pituitary secretion can lead to signs of other endocrine gland dysfunctions. These patients do not have hyperpigmentation as their ACTH is not elevated as in primary adrenal insufficiency.

In primary adrenal insufficiency, plasma concentrations of cortisol are usually low or in the low normal range. Response to ACTH stimulation is inadequate and is the definitive test for a diagnosis of adrenal hypofunction. After administering 250 μg of cosyntropin (Cortrosyn; synthetic ACTH 1–24) intravenously to the patient, an adequate adrenal response shows a 10 μg increase of cortisol over baseline at 30 or 60 minutes, or a stimulated cortisol level of 18-20 μg per dL.

The altered adrenal response to ACTH of critically ill patients limits interpretation of standard stimulation tests. Recognition of the complexity of adrenal hypofunction has led to reconsideration of its diagnosis in the ICU. Serum-free cortisol measurement is shown to be more accurate than total serum cortisol in determining cortisol adequacy [12]. ICU patients often have hypoproteinemia. Most circulating cortisol is bound to protein. Changes in protein abundance or dynamics therefore affect interpretation of total cortisol measurements. A serum-free cortisol of <9 μg per dL is sufficient to initiate glucocorticoid replacement [13].
However, measurement of free cortisol is unavailable in most hospitals. A random total cortisol of <10 μg per dL is useful as a threshold for glucocorticoid therapy. It is a practical guideline, but not supported by extensive clinical study. The American College of Critical Care considers this recommendation to be weak with moderate quality of evidence [11]. The concept of situational adrenal insufficiency is an idea inchoate, but a threshold concentration of total cortisol provides a mark for intervention. The term *critical illness-related corticosteroid insufficiency* is preferred for assessing adrenal function among the severely ill, because of the uncertainties of diagnosis.

Other diagnostic clues are useful in the diagnosis of adrenal crisis in ICU patients. Computed tomography scan can reveal adrenal hemorrhage or infiltration. Electrolytes vary, but hyponatremia is found in primary adrenal failure with hyperkalemia (sometimes not to a major degree) and in secondary adrenal failure without hyperkalemia. Hypoglycemia, elevated blood urea nitrogen, hypercalcemia, eosinophilia, lymphocytosis, and a normocytic, normochromic anemia are frequently present.
TREATMENT

The management of the hypoadrenalism has been vetted by a committee of international experts and the American College of Critical Care Medicine [11]. Recommendations have been provided as guidelines for the usefulness of glucocorticoid therapy in hypoadrenal function and critical illness (Table 139.1). There is agreement that hypoadrenalism needs to be treated as soon as it is raised as a possible problem. Diagnostic tests for ACTH and cortisol should be tested before administering glucocorticoids if possible to aid in the diagnosis.

TABLE 139.1 Summary of Advances in Managing Hypoadrenal Crisis

- Primary adrenal hypofunction in crisis (glucocorticoid and aldosterone insufficiency) presents with hypotension, fever, volume depletion, and often stupor and coma [9,21].

- The most common cause of secondary adrenal failure is glucocorticoid suppression, which can occur in as few as 5 d after prednisone treatment and last up to 1 y after chronic glucocorticoid withdrawal [22–24].

- Because cortisol is bound to corticosteroid-binding globulin and albumin, which is often reduced in critical care patients, interpretation of the cosyntropin stimulation test should consider the serum albumin concentration [12].

- Supplementation with glucocorticoid and mineralocorticoid improves survival in a subset of critically ill patients (renal failure, hypotension with poor response to pressor agents, lactic acidosis) who have documented inadequate cortisol response to cosyntropin [25].

- In patients with functional adrenals, use of glucocorticoids has not been established with high-quality data. Use of glucocorticoids early in severe shock might be useful [11,14].
For critical illness in which primary adrenal function is suspected (e.g., evidence of hemorrhage), a bolus of 100 mg of hydrocortisone should be administered intravenously and then 100 mg over the next 24 hours. The patient ought to receive isotonic saline to maintain volume. After the initial therapy and stabilization of the patient, hydrocortisone can be decreased by 50% each day. Maintenance is 20 to 30 mg per day.

Fludrocortisone 0.1 mg per day is started at the time of the maintenance glucocorticoid dose. In the corticosteroids and intensive therapy for septic shock trial, patients in shock were randomly assigned to high-dose hydrocortisone or high-dose hydrocortisone plus fludrocortisone. There was no difference in clinical outcomes. This trial supports the theory that hydrocortisone alone has sufficient mineralocorticoid effect.

Dexamethasone can be used in place of hydrocortisone therapy if adrenal reserve of cortisol needs to be studied. Dexamethasone does not interfere with cortisol testing. Isotonic saline infusion is necessary with glucocorticoid administration and will maintain circulating volume. Fludrocortisone (because its main activity is regulation of gene transcription) does not act quickly. Fludrocortisone would need to be given with dexamethasone because dexamethasone does not have mineralocorticoid properties.

Based on data from three small trials and the French trial, patients in septic shock who received hydrocortisone had a 10% absolute reduction in mortality compared with patients who had not received hydrocortisone. However, in the trials Corticus and Hypress, there was not a significant decrease in mortality in those patients who received hydrocortisone over those who did not. A meta-analysis of all the trials concludes that there is improvement in early shock reversal with glucocorticoids. This is a weak recommendation based on weak or moderate quality evidence. Intravenous hydrocortisone (50 mg q6h) has been advocated for patients with septic shock [14]. Of note, those patients with secondary adrenal insufficiency should have evaluation and replacement of other pituitary hormone deficiencies. Replacement of thyroid hormone without replacement of glucocorticoids can bring about acute adrenal crisis.
GLUCOCORTICOID USE FOR STRESSED PATIENTS ON GLUCOCORTICOID TREATMENT

General Principles

For healthy subjects, the secretion rate of cortisol increases from 10 mg per day to 50 to 150 mg per day during surgical procedures, but rarely exceeds 200 mg per day [18]. The degree of response depends, in part, on the extent and duration of surgery.

Historically, the withdrawal of chronic glucocorticoid therapy (and adrenal suppression) has been linked to the development of shock. Although in theory glucocorticoid withdrawal could lead to hypotension, documentation is sparse. Shock among acutely ill or surgical patients on steroid therapy (or within 1 year of withdrawal) should not be attributed solely to decreased adrenal responsiveness. Adrenal glucocorticoids should be administered, but other causes of hypotension should be sought. Suppression of the hypothalamic–pituitary–adrenal axis can occur after only 5 days of glucocorticoid treatment. After their long-term administration, the hypothalamic–pituitary–adrenal axis may respond inadequately to appropriate stimulation up to 1 year after glucocorticoid withdrawal. Adrenal suppression cannot be predicted based on glucocorticoid dosage and duration, or the measurement of a normal serum cortisol [19].

Diagnosis and Treatment

The patients with high risk for adrenal suppression are those who have taken pharmacologic or replacement doses of glucocorticoids for at least 4 weeks or stopped this treatment within the prior year. The cosyntropin test provides an assessment of adrenal cortisol reserve and estimates the adequacy of a stress response. A subnormal response predicts the need for supplemental glucocorticoids.

For minor surgical procedures, the patient’s usual dose of glucocorticoid is often sufficient, but a single dose of 25 mg hydrocortisone or its equivalent can be given. For moderate surgery, divided IV doses of hydrocortisone 50 to 75 mg are recommended on the day of surgery and the first postoperative day and then returning to the usual dose if the patient is hemodynamically stable. For major surgery, 100 to 150 mg hydrocortisone are recommended given in divided doses
for 2 to 3 days and then returning to the usual dose if possible. Excessive glucocorticoid dosing can have untoward effects [20]; more is not necessarily better.
REFERENCES

Disorders of mineral metabolism, although common, are rarely the primary cause of admission to an intensive care unit (ICU). However, these disorders frequently exacerbate life-threatening injuries and illness. Calcium, magnesium, and phosphorus are the main, clinically relevant minerals that can have an important impact on general health and on the course of a critical illness. Calcium ions regulate membrane potentials, the coagulation cascade, neurotransmitter release, hormone–receptor interactions, and intercellular communication through channels and ion exchange. Magnesium is necessary for parathyroid hormone (PTH) secretion and maintenance of serum calcium, neuromuscular function, and membrane sodium-potassium adenosine triphosphatase (ATPase) activity. Phosphate, the major intracellular anion, is also instrumental for normal cellular function. It is a component of nucleic acids, phospholipids, and high-energy nucleotides, and is necessary for oxidative metabolic pathway function. Phosphorus can also bind calcium in the body, and thus, phosphorus metabolism is related to calcium and magnesium homeostasis. Therefore, symptoms of abnormal phosphorus metabolism often reflect the abnormalities in circulating calcium and magnesium. Calcium, magnesium, and phosphate balance are controlled through the interactions of PTH, 1α,25-dihydroxyvitamin D (1,25 D), calcitonin, and fibroblast growth factor 23 (FGF-23).

CALCIUM DISORDERS

Calcium Physiology

Ninety-eight percent of total body calcium is stored in bone, whereas about 1% is located in extracellular fluids [1]. Approximately half of the
calcium in the extracellular fluids is bound to albumin or other anions with the remaining free/ionized calcium being biologically active [2]. Acid–base balance affects the binding of calcium to albumin [3]. Hyperventilation, and the resultant respiratory alkalosis, enhances the binding of calcium to albumin, thereby acutely decreasing the ionized calcium and causing symptoms of hypocalcemia despite unchanged levels of total calcium. Similarly, changes in serum protein levels affect total serum calcium. The measured total calcium level in the serum can be corrected to account for changes in serum proteins by using the following formula:

\[
\text{Corrected total calcium (mg/dL)} = \text{Measured total calcium (mg/dL)} + (0.8 \times [4 - \text{measured albumin (g/dL)}]) \quad [4]
\]

Although the formula takes into account changes in serum proteins, it does not consider the impact of alterations in pH that frequently occur during acute illness. Measuring the ionized calcium directly is another option that should not be affected by either the serum proteins or the pH.

Calcium homeostasis is a function of absorption from the intestine (primarily the small intestine by active transport and facilitated diffusion), bone resorption/formation, and urinary excretion. The average diet contains 500 to 1,500 mg of calcium per day. For young individuals, the efficiency of intestinal absorption varies inversely with the amount of calcium ingested. Approximately 300 mg of calcium is exchanged daily between plasma and bone. Serum calcium is in equilibrium with intracellular calcium and calcium in bone and is filtered through the kidney. Urinary calcium excretion (normally 100 to 300 mg of calcium per day) depends on the glomerular filtration rate and the tubular sodium reabsorption. Loop diuretics enhance urinary calcium excretion in conjunction with their effect on sodium excretion.

**Hormonal Regulation of Calcium**

Calcium absorption, excretion, and bone resorption/formation are in large part regulated by three hormones: PTH, 1,25 D, and calcitonin.

**Parathyroid Hormone**

PTH is an 84-amino acid polypeptide produced and secreted by the chief cells of the parathyroid gland [5]. Secretion of PTH is suppressed by the calcium-sensing receptor, thereby stimulated by low levels of serum calcium. The rapid release of PTH in response to hypocalcemia is essential for calcium homeostasis. The target organs for PTH are bone and kidneys. Chronic PTH secretion stimulates osteoclasts via the production of receptor activator of nuclear factor kappa ligand (RANKL)
from osteoblasts [6]. This results in bone resorption and dissolution of hydroxyapatite crystals resulting in the release of calcium and phosphate. The renal effects of PTH include decreased proximal tubular reabsorption of phosphate (phosphate wasting), enhanced distal tubular calcium reabsorption (calcium retention), and increased renal 1α-hydroxylase activity (enhanced 1,25 D production). It is through the increased production of 1,25 D that PTH indirectly increases intestinal absorption of calcium.

As opposed to the catabolic effects that PTH can have on bone through stimulating RANKL production, anabolic effects occur with intermittent administration of low-dose PTH. Intermittent administration of PTH does not impact RANKL as it does with constant administration, likely explaining the differing effects on bone mass [6]. In fact, daily subcutaneous injections of PTH derivatives have been shown to increase bone mineral density and decrease fracture risk in various populations [7,8].

Magnesium is mandatory for PTH secretion and end-organ response. Studies have shown that hypomagnesemia impairs PTH secretion and the renal response to PTH administration. Much of this is often reversible with magnesium repletion [9]. Clinically, correction of the hypocalcemia can often only be achieved after correcting hypomagnesemia.

**Vitamin D**

Vitamin D is a steroid hormone that is essential for calcium balance and is also likely important in numerous other cellular functions [10]. Activation of vitamin D requires 25-hydroxylation in the liver and 1-hydroxylation in the kidney to form the active hormone 1,25 D. Negative feedback is exerted by 1,25 D on its own production by suppressing 1α-hydroxylase activity and stimulating the enzyme 24-hydroxylase to produce the biologically inactive steroids 24,25(OH)₂D and 1,24,25(OH)₃D. FGF-23 also suppresses 1,25 D synthesis [11], though this is discussed in more detail as part of its role in phosphorus physiology.

The effects of 1,25 D are exerted through interactions with nuclear receptors located in a variety of cells, including enterocytes, parathyroid chief cells, osteoblasts, and renal tubular cells. 1,25 D increases intestinal absorption of calcium and phosphate. It has also been shown to suppress PTH gene expression as a negative feedback mechanism [11].

**Calcitonin**
Calcitonin is a 32-amino acid polypeptide produced by the C-cells of the thyroid [12]. It is secreted in response to elevations in serum calcium. It can also be stimulated by certain gastrointestinal (GI) tract hormones (e.g., gastrin). The primary physiologic function of calcitonin in humans remains unclear. Medullary carcinoma of the thyroid is a malignant neoplasm of the C-cells and is characterized by elevated calcitonin levels. However, calcium, phosphate, and PTH levels remain normal. Also, patients can have undetectable levels of calcitonin after a thyroidectomy with no clear detrimental systemic effects.

Despite the lack of clinical consequences from endogenous calcitonin excess or deficiency, exogenous calcitonin is a potent inhibitor of bone resorption. It also acts on the kidneys to enhance excretion of calcium, phosphate, magnesium, and sodium [12]. Both of these mechanisms make calcitonin useful in the treatment of hypercalcemia. The effect of calcitonin on bone resorption is lost over time due to tachyphylaxis [12]. This phenomenon, possibly due to downregulation of calcitonin receptors, is of clinical importance when treating patients with hypercalcemia. The excellent short-term effects of calcitonin to lower serum calcium (within 12 to 48 hours) allows the institution of therapies that require several days to attain maximal effectiveness (e.g., bisphosphonates).

Calcitonin can also be used for the treatment of osteoporosis. The administration of a salmon calcitonin nasal spray has been shown to decrease markers of bone turnover, increase bone mineral density at the spine, and decrease the risk of vertebral fractures in postmenopausal women with osteoporosis [13].

Hypercalcemia

Hypercalcemia is an abnormality of the balance between different body compartments and can result from increased bone resorption, decreased renal excretion, increased GI absorption, or any combination of these mechanisms.

The signs and symptoms of hypercalcemia are protean and can be divided into four groups: (a) mental, (b) neurologic and musculoskeletal, (c) GI and urologic, and (d) cardiovascular. The mental manifestations of hypercalcemia include stupor, obtundation, apathy, lethargy, confusion, disorientation, and coma. In general, for a given level of hypercalcemia, older patients exhibit more of the mental signs than younger patients. The neurologic and musculoskeletal effects of hypercalcemia are reduced muscle tone and strength, myalgias, and decreased deep tendon reflexes. The GI and urologic signs are vomiting, constipation, polyuria, and polydipsia. The major cardiovascular effect of hypercalcemia, which the intensive care physician must address, is shortening of the QT interval. In
the presence of ventricular ectopic beats, calcium-induced shortening of
the QT interval increases the potential for fatal arrhythmias or asystole.

**Differential Diagnosis**

Elevated serum calcium measurements have been reported in
approximately 1% of the general population \[14\]. The causes of
hypercalcemia can be differentiated into two broad groups defined by
whether or not the process is driven by abnormal parathyroid tissue.
Hence, the groups are termed: (a) PTH-independent hypercalcemia; and
(b) PTH-dependent hypercalcemia. In PTH-independent hypercalcemia,
the hypercalcemia is not mediated by abnormal parathyroid tissue, and
the PTH level should be appropriately suppressed. In PTH-dependent
hypercalcemia, the process is driven by dysregulated parathyroid tissue,
and the PTH level should be elevated, or inappropriately normal.

PTH-independent hypercalcemia is more common among hospitalized
patients. Hypercalcemia of malignancy is the most common cause of
PTH-independent hypercalcemia. The malignancies most often
associated with hypercalcemia include lung (35%), breast (25%),
hematologic (myeloma and lymphoma \[14\%\]), head and neck (6%), and
renal (3\%) \[15\]. The hypercalcemia can be mediated by secretion of
parathyroid hormone–related peptide (PTHrP), most commonly seen in
squamous cell carcinomas (often lung or head and neck tumors);
autonomous activation of 1,25 D (occasionally seen with lymphomas); or
by lytic bone lesions/metastases \[16\]. See Chapter 95 for a complete
discussion of the hypercalcemia of malignancy.

Other possible causes of PTH-independent hypercalcemia include
granulomatous diseases, immobilization, milk-alkali syndrome,
thyrotoxicosis, vitamin D or vitamin A intoxication, or Addison’s disease.

Granulomatous diseases such as sarcoidosis, tuberculosis, etc., can
cause hypercalcemia due to autonomous 1,25 D production by the
granulomas (similar to certain lymphomas). These patients have
increased intestinal calcium absorption and sensitivity to vitamin D
intake. Hypercalcemia occurs in 10\% of patients, though hypercalciuria
has been documented in as many as 20\% \[17\].

Immobilization causes hypercalcemia as a result of decreased bone
formation and persistent bone resorption. Hypercalcemia in the
immobilized individual occurs most commonly among patients with high
bone turnover (e.g., adolescents during the growth spurt or individuals
with Paget’s disease or thyrotoxicosis).

PTH-dependent hypercalcemia is much more common among
outpatients, although these patients can be hospitalized due to other
issues. PTH-dependent hypercalcemia can be caused by primary or
tertiary hyperparathyroidism. Another possible cause is familial
hypocalciuric hypercalcemia (FHH). The routine measurement of serum calcium has altered the clinical presentation of hyperparathyroidism with most patients presenting with asymptomatic hypercalcemia.

Primary or tertiary hyperparathyroidism results from autonomous secretion of PTH despite elevated serum calcium levels. The latter occurs typically after chronic secondary hyperparathyroidism in the setting of end-stage renal failure. Hypercalcemia develops due to increased bone resorption, increased intestinal calcium absorption from stimulation of 1,25 D production, and increased renal tubular calcium reabsorption. The patient can be hypophosphatemic due to the phosphaturic effect of PTH. The hormone also induces renal bicarbonate wasting, resulting in a mild hyperchloremic acidosis. In primary hyperparathyroidism, a single adenoma is present in 80% to 85% of cases, whereas four-gland hyperplasia occurs in 10% to 15% of cases [18]. Parathyroid cancer is present among less than 1% of these patients and typically presents with much higher serum calcium levels [19].

Parathyroid hyperplasia or adenomas can also occur as part of the multiple endocrine neoplasia (MEN) syndromes. Type I MEN involves tumors of the pituitary, pancreas, and parathyroids (usually hyperplasia), whereas type II is associated with pheochromocytoma, medullary cancer of the thyroid, and primary hyperparathyroidism (hyperplasia or adenoma) [20].

FHH is an autosomal dominant disorder characterized by hypercalcemia with inappropriately normal or elevated PTH levels. It is usually caused by an inactivating mutation in the calcium-sensing receptor gene [21], thereby requiring higher serum calcium levels to suppress secretion of PTH (i.e., an increased set point of serum calcium). In contrast to primary hyperparathyroidism, patients with FHH have relative hypocalciuria (fractional excretion of calcium <0.01), do not seem to be at increased risk of nephrolithiasis or bone disease, and cannot be cured surgically, unless rendered hypocalcemic by removal of all parathyroid tissue [22].

Several medications can induce hypercalcemia as well. Hypercalcemia associated with the use of thiazide diuretics is often an indicator of underlying primary hyperparathyroidism. Vitamin D and vitamin A intoxication can also cause hypercalcemia. Lithium may also affect parathyroid function and is associated with hypercalcemia and either elevated, or inappropriately normal, PTH levels (PTH-dependent hypercalcemia) [23].
Laboratory Evaluation

Hypercalcemia should always be considered for the patient with altered mental status. A total serum calcium level alone usually makes the diagnosis. However, altered binding of calcium to proteins, as can occur with hypoalbuminemia or with abnormal proteins (e.g., myeloma), or an acid–base imbalance may affect the free calcium level. Ionized calcium levels should not be affected by these issues. Because of the interrelationships of calcium, magnesium, and phosphorus, the latter two minerals should be measured in all cases involving altered calcium metabolism. An electrocardiogram to determine the QT interval is very important to assess the severity and urgency of the patient’s hypercalcemia.

The differential diagnosis of the hypercalcemia can be narrowed down with a serum intact PTH measurement. If PTH levels are physiologically suppressed by the hypercalcemia, then PTH-independent sources should be sought, with malignancy being the most common. If malignancy is suspected, obtaining PTHrP and 1,25 D levels can provide useful clues. In the absence of PTH, elevated 1,25 D levels imply autonomous production, most commonly associated with lymphomas and granulomatous diseases [16,17]. A bone scan may identify a metastatic process. Because myeloma is characterized by bone resorption with little bone formation, the bone scan is usually negative, but a skeletal survey may find lytic lesions. The diagnosis would then be confirmed by urine immunoelectrophoresis, serum protein electrophoresis, and bone marrow examination.

The diagnosis of milk-alkali syndrome is made by the patient’s history, often revealing large quantities of calcium carbonate ingestion. In this instance, the patient should also be alkalotic with an elevated bicarbonate level. Thyrotoxicosis and Addison’s disease can be ruled out with thyroid function tests and a cosyntropin stimulation test, respectively (see Chapter 139 for a discussion about evaluating adrenal function in the critically ill). Vitamin D intoxication is quite rare, but the possibility can be eliminated by measuring 25-hydroxyvitamin D levels. Vitamin A levels can be measured if the diagnosis remains unclear.

If PTH-dependent hypercalcemia is confirmed with elevated or inappropriately normal PTH levels, a 24-hour urine for a fractional excretion of calcium can be done to differentiate primary or tertiary hyperparathyroidism from FHH, though this test may be altered by renal failure or the use of various diuretics.

Management

The aim of treatment of hypercalcemia is to minimize its effects on central nervous system (CNS), renal, and cardiovascular function.
Appropriate treatment of hypercalcemia depends, in part, on the cause. General concepts in the management involve attempts to (a) increase renal calcium clearance, (b) decrease bone resorption, and (c) decrease intestinal calcium absorption. To this end, it is critical that the pathophysiology of the disease process be understood. If, for example, the hypercalcemia in a patient with myeloma is due to a combination of increased bone resorption plus decreased renal calcium clearance, successful management of the hypercalcemia requires that both processes be treated. Specific measures directed toward the pathophysiology of the hypercalcemia are discussed.

Hydration and Diuresis. Saline hydration creates a diuresis that increases renal calcium excretion by decreasing calcium reabsorption in the proximal tubule. Hydration plays a critical role in the initial management of hypercalcemia because the onset of the therapeutic response is rapid. The aim of therapy is to achieve a urine output >75 mL per hour. This often requires the administration of 200 to 500 mL per hour of normal saline [16,24]. Because a potential complication of administration of this amount of saline is congestive heart failure, extreme care must be taken in treating the patient with underlying cardiac disease or renal insufficiency. The concomitant administration of a loop diuretic helps prevent volume overload and further increases renal calcium excretion by inhibiting distal tubular calcium reabsorption. Although the clinical benefits of using this routinely are debated [16,25], furosemide 20 to 40 mg administered by the intravenous (IV) route has been used historically once rehydration has been achieved [24], especially if volume overload develops. Measurement of serum electrolytes, phosphorus, and magnesium is mandatory during saline hydration to replace adequately the quantities lost in the urine. If renal or cardiac failure precludes the use of saline hydration, dialysis with a calcium-free dialysate is an effective alternative.

Calcitonin. Calcitonin reduces the resorption of calcium from bone by inhibiting osteoclasts. It also exerts transient effects to increase the renal excretion of calcium, along with sodium, potassium, magnesium, and phosphate. The benefits of calcitonin for the treatment of hypercalcemia include (a) rapid onset within 2 hours, (b) maximal effect within 24 to 48 hours, and (c) low toxicity [12]. It can be used safely in patients with renal failure, and its side effects are limited to transient nausea, facial flushing, and occasional hypersensitivity at the injection site. The dose is 4 to 8 IU per kg body weight subcutaneously or intramuscularly every 12 hours [16]. Usually calcitonin is effective for only 4 to 7 days [12], but it is still used for the rapid response, as bisphosphonates often require several days to attain maximal effectiveness.

Bisphosphonates. Bisphosphonates are synthetic analogues of
pyrophosphate that are potent inhibitors of bone resorption through inhibition of osteoclastic activity and survival [16]. Because of the delay of reduction in serum calcium with bisphosphonates, these agents are often used in conjunction with other therapies. Pamidronate can be infused intravenously as 60 or 90 mg over 2 to 6 hours [16]. Zoledronic acid at a dose of 4 mg intravenously over not less than 15 minutes has been shown to be more effective at normalizing serum calcium in patients with hypercalcemia of malignancy [26]. Renal function must be monitored, and the doses of either medication may be repeated after a minimum of 7 days to allow a full response to the initial dose [16]. With long-term use, there is an increased risk of developing osteonecrosis of the jaw [27].

**Denosumab.** Denosumab is a monoclonal antibody directed against RANKL, preventing the binding of RANKL to osteoclasts, thereby inhibiting their development/activity and decreasing bone resorption. This agent is approved for the treatment of postmenopausal women with osteoporosis and has been shown to reduce the incidence of vertebral, non-vertebral, and hip fractures [28]. It has also been approved for the prevention of skeletal-related events in patients with bone metastases from solid tumors [29]. Recently, a single-arm study of 33 patients with hypercalcemia of malignancy refractory to bisphosphonates showed that 64% of subjects had a complete response to a dose of 120 mg subcutaneously on days 1, 8, 15, 29, and every 4 weeks for a median of 8 weeks [30]. The short-term adverse events were worsening hypercalcemia and dyspnea, but like bisphosphonates, long-term use is associated with an increased risk of developing osteonecrosis of the jaw [27]. This study prompted FDA approval in December 2014 for patients with hypercalcemia of malignancy refractory to bisphosphonates [16].

**Cinacalcet.** Cinacalcet is an agonist of the calcium-sensing receptor (also called a calcimimetic). In PTH-dependent hypercalcemia, it will suppress PTH secretion and lower serum calcium levels [31]. It has been approved for the chronic treatment of severe hypercalcemia in patients with primary hyperparathyroidism who are unable to undergo parathyroidectomy, but it has no role in the treatment of acute hypercalcemia and so will not be discussed further.

**Hypocalcemia**

Hypocalcemia is frequently encountered among critically ill patients. Although low serum albumin concentrations may explain some hypocalcemia, up to 18% of hospitalized patients and 85% of patients in...
ICUs were found to have hypocalcemia [32]. The symptoms of hypocalcemia can range from paresthesias and tetany, to seizures or fatal laryngospasm. A positive Chvostek’s sign (muscle spasm in response to tapping the facial nerve) is suggestive, but not diagnostic, of hypocalcemia. Trousséau’s sign (carpal spasm precipitated by inflation of a blood pressure cuff above the systolic blood pressure) is more sensitive and specific [32]. In contrast to the QT interval shortening in hypercalcemia, hypocalcemia is attended by an increase in the QT interval on the electrocardiogram, predisposing patients to cardiac arrhythmias. Chronic hypocalcemia is associated with basal ganglia calcification and cataract formation [4].

**Differential Diagnosis**

Risk factors for the development of hypocalcemia among hospitalized patients include alkalosis, renal failure, and multiple transfusions. Although pancreatitis is associated with hypocalcemia, the mechanism is unclear. Hyperphosphatemia is the suspected cause of hypocalcemia attending tumor lysis and rhabdomyolysis.

Inadequate, or absent, PTH secretion is a cause of hypocalcemia. Hypoparathyroidism is most common after neck surgery for thyroid or parathyroid disease, but it can also rarely be seen with neck irradiation, as a result of iron deposition in hemochromatosis or thalassemia, or in severe magnesium deficiency [4]. Idiopathic hypoparathyroidism can be familial or sporadic. An autoimmune phenomenon may explain the idiopathic variety and may be found together with other autoimmune endocrine dysfunction. Target tissue unresponsiveness due to a defect in the cell membrane G protein is characterized by hypocalcemia and hyperphosphatemia in the presence of elevated PTH levels. This is commonly known as pseudohypoparathyroidism, and can be associated with Albright’s hereditary osteodystrophy (short, stocky habitus; round facies; and short metacarpals, metatarsals, or both) [33].

Hypocalcemia can also signify vitamin D deficiency. Although nutritional rickets is rare in the United States, vitamin D deficiency is not [11]. Vitamin D deficiency may be the result of liver or renal failure with impaired hydroxylation of the parent compound, but is most often caused by inadequate sun exposure or malabsorption.

**Laboratory Evaluation**

A low corrected serum calcium or ionized calcium level confirms the diagnosis. Studies to discern the cause may include creatinine, phosphate, amylase, and magnesium levels; liver function tests; and 25-hydroxyvitamin D and PTH levels. In hypoparathyroidism due to the
absence of PTH or target tissue unresponsiveness, serum phosphate levels tend to be high as a result of absence of the phosphaturic effect of PTH.

Management

Treatment of hypocalcemia depends on its severity and chronicity. Symptomatic patients should be treated with IV calcium. A 10-mL vial of 10% calcium gluconate provides 93 mg of elemental calcium. One or two 10-mL vials should be administered in 100 mL 5% dextrose in water over 10 minutes [32]. Calcium to be administered intravenously should always be diluted because concentrated solutions are very irritating to veins. Electrocardiographic monitoring during calcium supplementation is recommended as arrhythmias can occur from overcorrection. Often, the initial bolus needs to be followed by a continuous infusion which can be started with 10 vials of calcium gluconate in 1 L of 5% dextrose in water running at 50 mL per hour. This can then be adjusted to maintain the serum calcium levels in the lower portion of the normal range [32]. Hypocalcemia may mask digitalis toxicity. In these situations, a slower rate of calcium administration is recommended to prevent cardiac arrhythmias.

Oral supplementation should be instituted concurrently to provide 500 to 1,000 mg of elemental calcium three times daily. If calcium supplementation alone cannot maintain serum calcium levels, vitamin D preparations may be administered. Ergocalciferol (vitamin D₂) has a wide safety margin and relatively low cost. The usual dose is 25,000 to 100,000 IU daily. This preparation has a slow onset of action because it must be 25-hydroxylated in the liver and 1α-hydroxylated in the kidney. The preparation has a long half-life because it is stored in fat. Activated vitamin D preparations that act more rapidly are also available. Calcitriol is 1,25 D₃ and can be given as 0.25 to 1.0 μg, once or twice daily. This has a shorter half-life than vitamin D but is more potent. It can be used for long-term management but has a narrower therapeutic window [4].

Up until recently, there was no approved hormone replacement for hypoparathyroidism. In 2013, a phase 3 trial of recombinant human PTH (1-84) showed that 53% of subjects with hypoparathyroidism were able to reduce their calcium and active vitamin D doses by >50% [34]. This prompted FDA approval of this medication in 2015 for patients with hypoparathyroidism who are not well controlled on standard treatment with calcium and active vitamin D [35].

The goal of treating hypocalcemia is to prevent symptoms attributable to low calcium and to avoid hypercalciuria and hypercalcemia. In the hypoparathyroid patient, total serum calcium should be maintained between 8.0 and 8.5 mg per dL. In the absence of PTH, circulating
calcium levels greater than 9.0 mg per dL are often attended by hypercalciuria and an increased risk of nephrolithiasis or nephrocalcinosis. If hypercalciuria occurs despite lower serum calcium concentrations, thiazide diuretics can be used to try and enhance tubular reabsorption of calcium [4]. This could be less of an issue if injectable PTH is used in the treatment regimen [35].
MAGNESIUM DISORDERS

Magnesium Physiology

Magnesium is the major intracellular divalent cation. Two-thirds of the total body content of magnesium is found in bone and only 2% is found in the extracellular space. Muscle and liver are the soft tissues that contain the greatest amount of magnesium. Thirty percent of extracellular magnesium circulates bound to protein [5]. Therefore, as with circulating calcium levels, the serum albumin concentration must be known to interpret total magnesium levels. Magnesium absorption occurs throughout the small intestine. Like calcium, magnesium is reabsorbed in the kidney tubules.

Magnesium is necessary for normal sodium- and potassium-activated ATPase, PTH secretion, and neuromuscular function. Decreased sodium- and potassium-activated ATPase due to hypomagnesemia can result in intracellular potassium depletion. Magnesium-induced decreases in PTH secretion result in hypocalcemia that can only be corrected by magnesium replacement. Hypomagnesemia is often attended by CNS hyperexcitability, whereas hypermagnesemia results in CNS depression. This can be independent of changes in serum calcium concentration [36].

Hypermagnesemia

Hypermagnesemia is often attended by a loss of deep tendon reflexes and CNS depression. Flaccid paralysis, hypotension, confusion, and coma may result from magnesium levels greater than 6 mg per dL [36]. The most common cause of hypermagnesemia in the hospitalized patient is renal failure. The hypermagnesemia may be aggravated by the administration of magnesium-containing antacids. Diabetic ketoacidosis is usually attended by hypermagnesemia, but this typically reflects dehydration, which masks the total body magnesium depletion resulting from the glucose-induced osmotic diuresis.

Management

The actions of magnesium on neuromuscular function are antagonized by calcium. Emergency treatment of the magnesium-induced CNS depression includes IV administration of one to two 10-mL vials of
Calcium gluconate diluted in 100 mL 5% dextrose in water over 5 to 10 minutes to prevent venous irritation [36]. The dose may be repeated as necessary. Total serum calcium must be monitored and not allowed to exceed 11 mg per dL.

Definitive treatment of the hypermagnesemia requires increasing renal magnesium excretion. In the presence of normal renal function, increased magnesium excretion can be achieved by IV administration of furosemide, 20 to 40 mg IV, every 1 to 2 hours, along with fluid hydration, though there is little literature to support its use [36]. Serum electrolytes, particularly potassium, must be closely monitored. Dialysis is the treatment of choice when kidney function is impaired and the patient is symptomatic from hypermagnesemia.

Hypomagnesemia

Hypomagnesemia is much more common than hypermagnesemia among hospitalized patients [5]. The increased CNS excitability in the patient with hypomagnesemia is partly due to the accompanying hypocalcemia, which results from impaired PTH secretion and decreased peripheral tissue responsiveness to PTH. The intracellular potassium depletion seen with hypomagnesemia can also exacerbate digitalis toxicity.

Hypomagnesemia may result from decreased intestinal absorption (e.g., steatorrhea), or more commonly from increased renal excretion due to an osmotic diuresis (e.g., hyperglycemia), or drugs (e.g., ethanol, aminoglycosides, or cisplatin). Dietary deficiency alone is rarely the explanation for hypomagnesemia. The exceptions are starvation or prolonged parenteral feeding [36].

The drugs that most commonly increase renal magnesium excretion are alcohol and diuretics. Hypomagnesemia in the alcohol abuser may also be partly attributable to dietary deficiency. Hypomagnesemia is encountered in 30% of alcoholics [36].

Management

Magnesium may be administered orally or parenterally. If serum magnesium levels are below 1.2 mg per dL, or if the patient is symptomatic, parenteral treatment is indicated. Because magnesium is predominately intracellular, the serum levels typically underestimate the deficit. Therefore, it is recommended to give 8 to 12 g of magnesium sulfate over the first 24 hours followed by 4 to 6 g per day for 3 to 4 days to replete body stores [36]. Serum magnesium and calcium levels should be monitored. The dose should be reduced by 75% in patients with renal failure.

In the patient with mild magnesium deficiency, oral therapy is usually
satisfactory. Magnesium oxide 400 mg (241 mg of elemental magnesium) can be given as one to two tablets daily. Diarrhea is the most common side effect. As with all magnesium supplementation, levels must be monitored closely in the patient with renal insufficiency.
PHOSPHORUS DISORDERS

Phosphorus Physiology

Eighty-five percent of total body phosphorus is found in bone. Extracellular phosphate accounts for only 1% of total body phosphorus [5]. Phosphorus is a component of nucleic acids and phospholipids and is a cofactor for a number of enzymes. Because of shifts in phosphate between intracellular and extracellular compartments, serum phosphate levels often do not accurately reflect total body stores. For example, because acidosis causes a shift in phosphate from within cells to the extracellular compartment, serum phosphate levels may be normal in the acidotic patient despite depletion of total body stores [3]. As the acidosis is corrected, serum phosphate levels may fall.

Phosphorus is also regulated by PTH and 1,25 D, as well as FGF-23. PTH stimulates phosphate excretion by the kidneys, similar to FGF-23 secreted by the osteocytes (classifying it as a “phosphatonin”) [5]. In addition, FGF-23 directly suppresses 1α-hydroxylase activity. Therefore, phosphate retention (as in renal failure) leads to an increase in FGF-23, thereby suppressing 1,25 D production and inhibiting phosphorus absorption in the intestine. In the setting of normal renal function, excess FGF-23 (as in X-linked hypophosphatemic rickets or tumor-induced osteomalacia) leads to excess phosphaturia, hypophosphatemia, and mineralization defects in bone [37].

Hyperphosphatemia

Increased phosphate levels are most often encountered among patients with renal failure or hypoparathyroidism. Both of these conditions result in impaired phosphate excretion. Hyperphosphatemia can also be seen from cellular leaks as in hemolysis, rhabdomyolysis, or the tumor lysis syndrome. The hyperphosphatemia, along with diminished renal 1,25 D production from increased FGF-23, results in hypocalcemia. The symptoms are usually attributable to the accompanying hypocalcemia, and not the hyperphosphatemia per se [38]. Therefore, in the symptomatic patient, therapy should be directed at correction of the hypocalcemia.

Chronic management of hyperphosphatemia can be accomplished with limiting phosphate intake as well as using phosphate binders, such as calcium acetate 667 mg, two tablets with meals, sevelamer 800 mg, one to two tablets with meals, or lanthanum carbonate 500 to 1,000 mg with meals [3,38].
Hypophosphatemia

Hypophosphatemia can be seen in up to 3% of hospitalized patients or 34% of patients in the ICU [39]. It can result from impaired intestinal phosphate absorption or increased renal phosphate excretion. The cause of hypophosphatemia in alcoholics is often multifactorial but most likely reflects malnutrition and the accompanying vomiting. When taken in excess, phosphate-binding antacids impair phosphate absorption. The resulting hypophosphatemia can stimulate 1,25 D production and cause hypercalcemia, which has been confused with hyperparathyroidism.

Renal phosphate excretion is increased in hyperparathyroidism, vitamin D deficiency, and with osmotic diuresis. There are also rare genetic and paraneoplastic conditions that cause increased phosphate excretion through excess FGF-23 levels [37]. PTH inhibits renal tubular phosphate reabsorption, resulting in hypophosphatemia when secreted in excess. Serum phosphate levels are reduced in vitamin D deficiency due to impaired intestinal phosphate absorption and increased renal phosphate excretion (the result of secondary hyperparathyroidism in response to the associated hypocalcemia). The patient in diabetic ketoacidosis has a total body phosphorus deficit, despite normal serum phosphorus levels. In the early stages of the illness, the rising serum glucose levels cause an osmotic diuresis with increased renal phosphate loss. However, the developing acidosis causes a shift in phosphorus from the intracellular to the extracellular compartment. This shift, along with the accompanying volume depletion, tends to normalize the serum phosphorus levels. Rehydration and insulin treatment with resolution of the acidosis may cause a rapid fall in serum phosphorus levels.

The potential consequences of severe hypophosphatemia are impaired oxygen delivery to the tissues due to decreased 2,3-diphosphoglycerate levels, muscle weakness, and rhabdomyolysis. The latter is most likely to occur when severe hypophosphatemia occurs after prolonged mild hypophosphatemia (e.g., in the hospitalized alcoholic in whom phosphate falls precipitously during carbohydrate administration).

Management

Severe hypophosphatemia (<1.5 mg per dL) requires parenteral therapy [3]. Potassium phosphate or sodium phosphate can be used depending on the patient’s potassium level. 15 mmol may be added to 5% dextrose in water and given intravenously over 2 hours [39]. Further treatment
depends on the serum phosphate levels and clinical condition. The dose may be repeated up to three times in the first 24 hours until phosphate levels normalize.

Parenteral therapy should be limited for the patient with renal failure or hypocalcemia. In the patient with renal failure, IV therapy can cause hyperphosphatemia, worsen hypocalcemia, and cause metastatic calcification, primarily in the kidney. The latter can occur if the patient is hypercalcemic or if the phosphate is administered too rapidly. Initial doses should be 50% lower if the patient is in renal failure or hypercalcemic [3].

Oral preparations of potassium phosphate (K-Phos Neutral) can be used for milder hypophosphatemia or for chronic management. The usual oral dose is 1 to 4 g per day in divided doses. The most common side effect is diarrhea.

16. Thosani S, Hu MI: Denosumab: a new agent in the management of

Patients with thyrotoxicosis rarely need hospitalization. However, some patients with severe thyrotoxicosis develop a decompensated clinical presentation called *thyroid storm*. It is characterized by hyperpyrexia, tachycardia, and delirium [1] and generally occurs among patients with severe thyrotoxicosis, who then experience a physiological insult. The cause of this rapid decompensation is unknown, but it may be partly because of a sudden inhibition in thyroid hormone binding to plasma proteins, resulting in a rise in the already elevated free hormone pool [2]. Thyroid storm accounts for no more than 2% of hospital admissions for all forms and complications of thyrotoxicosis, and the diagnosis is often difficult to make because there is a fine line between severe thyrotoxicosis and thyroid storm. Even when properly treated, thyroid storm has a mortality rate of 7% to 30% [3].

**ETIOLOGY**

Before the preoperative use of iodides and the antithyroid drugs propylthiouracil (PTU) and methimazole (MMI; Tapazole), thyroid storm was most frequently seen during and after subtotal thyroidectomy. Because these agents are used to restore euthyroidism before surgery, thyroid storm is rarely seen in this context. Thyroid storm now occurs most commonly among patients with severe underlying thyrotoxicosis, frequently undiagnosed, who become ill for other reasons, such as infections, trauma, labor, diabetic ketoacidosis, or pulmonary and cardiovascular disorders. It can occur during or after nonthyroid surgery, and has been reported after external beam radiation to the neck [4], ingestion of sympathomimetic drugs (such as pseudoephedrine) in a thyrotoxic patient [5], and rarely with intentional or accidental overdoses [6,7]. Thyroid storm may rarely occur approximately 10 to 14 days after the administration of iodine 131 in patients with large goiters who have
not been adequately pretreated with PTU or MMI to deplete the gland of stored thyroxine ($T_4$) and triiodothyronine ($T_3$) [8]. β-blockers are used to decrease symptoms of excess thyroid hormone release, but may not prevent thyroid storm.
CLINICAL MANIFESTATIONS

There is no absolute level of circulating thyroid hormones indicative of thyroid storm, and the diagnosis is made on a clinical basis [3]. Patients with thyroid storm are almost always febrile (temperature usually higher than 100°F) and have rapid sinus tachycardia and tachyarrhythmias (especially atrial fibrillation in elderly patients) out of proportion to the degree of fever that can frequently result in congestive heart failure. Patients are often agitated, delirious, and tremulous, with hot, flushed skin due to vasodilation. The skin may be moist or dry, depending on the state of hydration. Diarrhea occurs frequently and contributes to dehydration and hypovolemia. Vascular collapse and shock, which are poor prognostic signs, may occur. Hepatomegaly with abnormal liver enzymes and splenomegaly can be present; jaundice portends a poor prognosis.

Most patients display the classic signs of thyrotoxic Graves’ disease, including ophthalmopathy, or toxic uninodular or multinodular goiter. However, in elderly patients, apathy, severe myopathy, profound weight loss, and congestive heart failure may be the predominant findings. As thyroid storm progresses, coma, hypotension, vascular collapse, and death may ensue unless active therapy is instituted.
The diagnosis of thyroid storm is made on clinical grounds. Thyroid function tests do not differentiate between severe thyrotoxicosis and thyroid storm. Serum T₄ concentrations are usually similar, although it has been suggested that the serum-free T₄ concentration is significantly higher in patients with thyroid storm [2], which might partially explain their more severe symptoms. On the other hand, the serum T₃ concentrations are not higher and in fact may be less elevated or even normal in these patients when the precipitating cause is an intercurrent illness or surgery, because peripheral T₃ production from T₄ is markedly impaired in a wide variety of acute and chronic systemic illnesses. Liver function tests are frequently abnormal, especially in elderly patients with congestive heart failure. Elevations in total and free serum calcium concentrations may occur.

The differential diagnosis for a patient presenting with hyperpyrexia, delirium, and tachycardia includes severe infection, malignant hyperthermia [9], neuroleptic malignant syndrome, and acute mania with life-threatening catatonia. Thyroid storm can be distinguished from these disorders clinically by a history of thyroid disease, thyroid hormone, or iodine ingestion, and the presence on physical examination of a goiter or the stigmata of Graves’ disease, including ophthalmopathy, onycholysis, and pretibial myxedema. However, any of the disorders mentioned in the differential diagnosis can coexist with thyroid storm since they may precipitate decompensation for a patient with preexisting hyperthyroidism.
Treatment of thyroid storm is directed toward therapy of the underlying illness, supportive care, blocking peripheral effects of thyroid hormone, and inhibition of thyroid hormone synthesis and release (Table 141.1).

**Underlying Illness**

Nonthyroidal illness and surgery in previously undiagnosed or only partially treated patients with hyperthyroidism are the most common causes of thyroid storm. Thus, the precipitating disease should be vigorously treated. Cardiac arrhythmias and congestive heart failure require approximately twice the dose of digoxin needed in euthyroid patients or alternative management, and refractory arrhythmias should alert the physician to the presence of thyrotoxicosis. Patients may also
have peripheral resistance to heparin and insulin, and higher doses may be required. It is evident that these patients must receive adequate antibiotic therapy; careful fluid, electrolyte, and vitamin supplementation; vigorous pulmonary therapy; and careful pre- and postoperative care. If emergency surgery is required for a thyrotoxic patient, propranolol, PTU or MMI, iodides, and perhaps corticosteroids should be given before, during, and after surgery.

Supportive Care

A cooling blanket can be used if the temperature rises above 101°F, but the shivering response that results from central cooling should be decreased by using drugs that block the central thermoregulatory centers, such as chlorpromazine or meperidine, 25 to 50 mg every 4 to 6 hours. Antipyretics other than salicylates may also be given. Salicylates should be avoided because they displace thyroid hormones from serum-binding proteins and can increase the free hormone concentrations [10]. Dehydration is frequently present and should be treated with intravenous fluid while monitoring for congestive heart failure.

Blockade of Peripheral Effects of Thyroid Hormone

Many of the clinical manifestations of hyperthyroidism can be alleviated by the administration of drugs that deplete or block the peripheral action of the catecholamines. β-adrenergic blocking agents are currently the drugs of choice in alleviating the catecholamine-dependent signs and symptoms of thyrotoxicosis and thyroid storm. The widest experience has been achieved with propranolol, which also has the advantage of decreasing $T_4$ to $T_3$ conversion (see later). Tachycardia and tremors can be improved within minutes of intravenous administration. Oral doses in the range of 60 to 120 mg every 6 hours may be required [11].

Because propranolol may be contraindicated for patients with congestive heart failure, it is frequently debated whether to use β-blockers for patients with severe thyrotoxicosis or thyroid storm. However, tachycardia and tachyarrhythmias are major contributing factors to the congestive failure in many of these patients, so β-blockers may be used cautiously along with digoxin and other cardiotropic drugs and diuretics. Rarely, hypotension and cardiac arrest occur after intravenous administration of β-blockers among patients with severe congestive failure and severe thyrotoxicosis [12]. For patients with asthma, the more selective β$_1$-blocking drugs, such as metoprolol and atenolol, may be used. A short-acting β$_1$-blocker, esmolol [13], and diltiazem can also be used to control the tachyarrhythmias associated with thyrotoxicosis [14].
Inhibition of Thyroid Hormone Synthesis

The antithyroid drugs, PTU and MMI, are potent inhibitors of the synthesis of both T₄ and T₃. Although the onset of action is rapid, PTU and MMI only partially block thyroid hormone synthesis. Weeks are required to deplete the thyroid of stored hormone and observe clinical effects of these drugs. Intravenous MMI is available in Europe, but in the United States, administration by either nasogastric tube or by rectum may be used [15]. PTU has the added advantage of partially blocking the peripheral conversion of T₄ to T₃ and therefore may be the drug of choice, although a recent retrospective study showed no difference in mortality or disease severity in patients treated with MMI versus PTU [16]. These drugs are not effective if thyroid storm is caused by excess ingestion of thyroid hormone (see the section Thyrotoxicosis Factitia) or painful or silent thyroiditis because they affect the synthesis of thyroid hormone and do not affect its release or peripheral activity.

Blockade of Thyroid Hormone Release

Iodide administration plays a major role in the treatment of thyroid storm because of its rapid inhibition of thyroid hormone release from the gland. This effect occurs almost immediately after oral or intravenous administration. Some inhibition of hormone synthesis may also occur in the hyperfunctioning gland. As with PTU and MMI, iodide therapy is not useful in thyroid storm caused by ingestion of excess amounts of thyroid hormone (thyrotoxicosis factitia) because it affects the synthesis and release of endogenously synthesized thyroid hormone.

Lugol’s solution or saturated solution of potassium iodide can be given orally or as a potassium iodide enema, 1 g in 60 mL of water, followed by 500 mg of potassium iodide in 20 mL of water every 6 hours, given rectally in a patient who is unable to receive oral medication. Iodide therapy results in dramatic improvement and should be maintained until the serum T₄ and T₃ concentrations are normal or near normal. However, iodides can exacerbate hyperthyroidism when the patient is not pretreated with PTU or MMI and also delay the option of radioactive iodine for subsequent, definitive treatment. Escape from the iodide effect often occurs when PTU or MMI is not concomitantly used [17]. In patients allergic to iodine, lithium has been used to inhibit thyroid hormone release and partially inhibit thyroid hormone synthesis [18].
Inhibition of Peripheral Generation of Triiodothyronine

It is generally believed that the major bioactive hormone is $T_3$, that the major source of circulating $T_3$ is derived from $T_4$, and that most, if not all, of the metabolic effects of $T_4$ result from the intracellular generation of $T_3$ from $T_4$. A variety of drugs impair the outer-ring monodeiodination of $T_4$ to $T_3$, thus decreasing the peripheral generation of $T_3$. Propranolol, some selective $\beta_1$-blocking drugs [19], and PTU are relatively weak inhibitors of $T_4$ to $T_3$ conversion. The corticosteroids, especially dexamethasone, are potent inhibitors when administered at high doses and also have an inhibitory effect on thyroid hormone hypersecretion. Their importance for treating thyroid storm has been well documented; the survival rate for thyroid storm was improved when corticosteroids were added to the treatment regimen. Because relative adrenal insufficiency may be present in patients with thyroid storm, glucocorticoid therapy would also correct this possibility. Indeed, combination therapy of severe hyperthyroidism with PTU, iodides, and dexamethasone has resulted in a marked reduction of serum $T_3$ concentration within 24 hours.

The gallbladder dyes, iopanoic acid (Telepaque), and ipodate (Oragrafin), are potent inhibitors of $T_4$ to $T_3$ conversion and successfully used in treatment of thyroid storm [20], but are no longer available in the United States. Similarly, amiodarone also decreases $T_3$ levels. In addition, it is rich in iodine, and may also block entrance of $T_4$ into the cell. Although this drug has been used in the short-term (2 weeks) treatment of thyrotoxicosis, it should not be used in the treatment of thyroid storm because its long half-life and high iodide content can cause persistent, severe hyperthyroidism [21].

Removal of Thyroid Hormone from the Circulation

Direct removal of thyroid hormone from the circulation is occasionally required in patients who do not respond to conventional medical treatment. There are case reports of successful use of plasmapheresis [22] and charcoal plasma perfusion [23]. Cholestyramine, which binds $T_3$ and $T_4$ in the gut and decreases serum $T_3$ and $T_4$ concentrations by increasing the fecal excretion of these hormones [24], may also be useful, particularly if used early in a patient with an overdose.

Thyrotoxicosis Factitia

The inadvertent ingestion of excess amounts of thyroid hormone most
commonly occurs in children, although adults may also ingest excess hormone for weight reduction or as a suicide attempt [6,7,25]. Gastric lavage or emesis induction should be performed as soon as possible after ingestion. Occasionally, oral charcoal administration can be useful. As previously mentioned, this form of thyrotoxicosis is not caused by endogenous production of thyroid hormone; therefore, drugs that inhibit the synthesis of T_4 and T_3 or those that block thyroid hormone release are not helpful. Therapy should focus on preventing the peripheral effects of excessive thyroid hormone with β-adrenergic blocking drugs and possibly corticosteroids. Cholestyramine may also be useful to decrease serum thyroid hormone levels, as above.
CONCLUSIONS

It is evident that each patient must be treated individually and that a set protocol cannot be advised for all patients. Specific therapy should be directed toward inhibiting the synthesis and release of $T_4$ and $T_3$ from the thyroid, blocking the peripheral conversion of $T_4$ to $T_3$, relieving the catecholamine-mediated effects by $\beta$-adrenergic blockade, and treating the possibility of decreased adrenal reserve with corticosteroids. Associated and precipitating diseases should, of course, be vigorously treated. Iodine often works quickly to improve thyroid hormone levels, but will delay the use of radioactive iodine treatment of hyperthyroidism and thus should be saved for patients with thyroid storm, not just severe thyrotoxicosis.

13. Vijayakumar HR, Thomas WO, Ferrara JJ: Peri-operative management...

Myxedema coma is a syndrome that occurs in advanced untreated hypothyroidism [1–5]. It is defined by a group of characteristic clinical features and not by laboratory evidence of severe hypothyroidism (Table 142.1). Myxedema coma is generally preceded by increasingly severe signs and symptoms of thyroid insufficiency. Fortunately, it is quite rare. Hypothyroid patients who are neglectful or whose contact with family and friends is limited are most vulnerable. Despite early and intensive treatment, mortality from myxedema coma is still as high as 30% to 50% [2,4,6,7].

TABLE 142.1 Clinical Features of Myxedema Coma

- Mental obtundation
- Course, dry skin
- Myxedema facies
- Hypothermia
- Hypoglycemia
- Bradycardia and hypotension
- Electrocardiographic changes
- Atonic gastrointestinal tract
- Atonic bladder
- Pleural, pericardial, and peritoneal effusions

ETIOLOGY AND PATHOPHYSIOLOGY

By definition, myxedema coma does not occur in the absence of
hypothyroidism. If hypothyroidism is due to hypothalamic or pituitary insufficiency, the condition is even more serious because it is also accompanied by adrenal failure. Pituitary tumors are the major cause of central hypothyroidism in the United States. In regions with poor access to health care, postpartum pituitary necrosis is quite prevalent and is therefore another important cause of secondary hypothyroidism.

More than 95% of patients with hypothyroidism have primary thyroid disease. Most patients with primary hypothyroidism have either autoimmune thyroid failure or hypothyroidism secondary to ablative procedures on the thyroid. These include radioactive iodine and surgery for hyperthyroidism, thyroid resection for thyroid cancer, and external thyroid irradiation for head and neck tumors. Certain drugs, such as lithium carbonate and amiodarone, can cause hypothyroidism but are only rarely associated with myxedema coma.

Myxedema coma is distinguished from uncomplicated hypothyroidism by a variety of features that relate to central nervous system (CNS) dysfunction. The pathophysiology of myxedema coma will become clearer when there is a better understanding of the effects of thyroid hormone on the brain. Narcotics and hypnotics should be used with caution in hypothyroid patients because these patients are very sensitive to their sedative effects. These agents, alone or in combination with other factors, may precipitate myxedema coma in hypothyroid patients. Other precipitating factors are trauma, surgery, and severe infection [1–9]. The most important factor in temperate climates, however, is cold stress. In one series, 9 of 11 patients with myxedema coma were admitted in the late fall or winter [2].
Patients are partially or completely obtunded. Therefore, the history must often be obtained from other sources. Friends, relatives, and acquaintances might have noted increasing lethargy, complaints of cold intolerance, and changes in the voice. An outdated container of L-thyroxine discovered with the patient’s belongings suggests that he or she has been remiss in taking medication. The medical record may also indicate that the patient was taking thyroid hormone or may refer to previous treatment with radioactive iodine. A thyroidectomy scar suggests the possibility of hypothyroidism. Other than coma itself, the cardinal manifestations are hypothermia and hypotension. Hypotonia of the gastrointestinal tract is common and often so severe as to suggest an obstructive lesion. Urinary retention due to a hypotonic bladder is related but less frequently observed. Most patients have the physical features of severe hypothyroidism, including bradycardia and slow relaxation of the deep tendon reflexes. A myxedematous facies (Fig. 142.1) results from the dry puffy skin, pallor, hypercarotenemia, periorbital edema, and patchy hair loss.
Characteristic facies of severe hypothyroidism. Note the facial and periorbital puffiness and the dull, lethargic expression.
DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of myxedema coma is based on the presence of the characteristic clinical syndrome in a patient with hypothyroidism. The laboratory’s role is to confirm that the patient is hypothyroid and determine whether there are treatable complications of myxedema coma, such as hypoventilation, hypoglycemia, and hyponatremia. Because of the gravity of myxedema coma, treatment must be instituted before laboratory tests confirm the diagnosis.

The diagnostic laboratory features of primary hypothyroidism are a subnormal serum-free thyroxine index or serum-free thyroxine ($T_4$) concentration and an elevated serum thyroid-stimulating hormone (TSH) concentration. The serum-free thyroxine index or free $T_4$ is also low in severely ill patients with a wide variety of conditions. This is the so-called “sick euthyroid syndrome” or nonthyroidal illness. Unlike patients with myxedema coma, however, serum TSH concentrations are not elevated among patients with the sick euthyroid syndrome, except in a small percentage, and usually as they are clearly recovering from their severe illness. Distinction between hypothyroidism secondary to pituitary or hypothalamic disease (i.e., central hypothyroidism) and the sick euthyroid syndrome is difficult because serum TSH concentrations are low or, when TSH bioactivity is reduced as in secondary hypothyroidism, only mildly elevated in patients with central hypothyroidism. It is important to measure TSH as well as the serum-free thyroxine or free thyroxine index for patients presenting with myxedema coma. In central hypothyroidism, the typical clinical presentation of the myxedematous patient would help establish the diagnosis. The sick euthyroid syndrome is discussed in Chapter 143. The measurement of the total serum triiodothyronine ($T_3$) concentration is of no value for the diagnosis of hypothyroidism or myxedema coma. It lacks sensitivity for the diagnosis of hypothyroidism and is depressed not only by illness but also by fasting.

Alone, few of the signs and symptoms described in this chapter are unique to myxedema coma. For example, the differential diagnosis of hypothermia (see Chapter 184) includes numerous conditions, such as malnutrition, sepsis, hypoglycemia, multisystem trauma, prolonged cardiac arrest, and exposure to alcohol and certain drugs or toxins [10,11]. Hypotension and hypoventilation, other cardinal features of myxedema coma, occur in other disease states. What distinguishes myxedema coma from other disorders is laboratory evidence of
hypothyroidism, characteristic myxedema facies with periorbital puffiness, skin changes, obtundation, and, frequently, a constellation of other physical signs characteristic of severe hypothyroidism. Recently, two scoring systems have been proposed for the diagnosis of myxedema coma, based on clinical features and laboratory or imaging findings. However, these are both based on small groups of patients, and their utility has not been well validated [12,13].
TREATMENT

As noted earlier, for most patients with myxedema coma, hypothyroidism is due to primary thyroid disease. The initial management of myxedema coma due either to primary thyroid disease or central (pituitary or hypothalamic) disease is similar, since glucocorticoids are recommended in all patients. The only proviso is that in patients with central hypothyroidism, additional evaluation of the CNS for the presence of space-occupying lesions is warranted. Therefore, the management team must be alert for evidence of space-occupying lesions within or in the region of the pituitary for all patients with myxedema coma.

Treatment of myxedema coma consists of management of hypoglycemia, respiratory depression, hyponatremia, hypothermia, hypotension, and administration of thyroid hormone (Table 142.2). All patients require continuous monitoring of the electrocardiogram and an intravenous line to administer fluids and drugs. Baseline thyroid function tests, serum cortisol, complete blood count, blood urea nitrogen, creatinine, plasma glucose, and electrolytes are mandatory. Pneumonia commonly develops or may be the precipitating factor and must be treated promptly (see Chapter 181). Hypothyroidism and myxedema coma are also associated with hemostatic abnormalities, particularly capillary bleeding and cerebral hemorrhage \[2,14,15\]. Although bleeding should be anticipated in some patients, few strategies have evolved to counter this disorder.

ᵃDosage must be individualized (see text).

IV, intravenously; T₃, triiodothyronine; T₄, thyroxine.
Hypoglycemia

Because hypoglycemia is not unusual in myxedema coma, 50 mL of 50% glucose should immediately be administered intravenously when point of care glucose testing is not available to avoid any delay in treatment of this serious complication. Chapter 138 details the management of hypoglycemia.

Hypoventilation

Respiratory center depression is common in severe hypothyroidism and myxedema coma. Arterial blood gases should be routinely obtained, therefore, to rule out hypoventilation. If respiratory center depression is clinically obvious, assisted ventilation with oxygen supplementation must be started without delay, taking care not to correct chronic hypercapnia too rapidly (see Chapters 165, 166, 167).

Hyponatremia

Hyponatremia, which results from impaired free water clearance, is most deleterious to CNS function when it develops rapidly. Although hyponatremia is present in some patients, it is usually not the cause of coma because its onset tends to be gradual. A limiting factor is that water intake decreases as myxedema coma develops, offsetting the tendency toward hyponatremia. Treatment consists of restriction of free water. If the serum sodium concentration is less than 110 mEq per L, hypertonic saline and, in some cases, furosemide should be administered (see Chapter 199).

Hypothermia

Hypothermia is one of the hallmarks of myxedema coma. It can be overlooked or its severity underestimated, however, if an out-of-date or poorly calibrated thermometer is used. Regardless of the cause, hypothermia is associated with a decrease in the basal metabolic rate, myocardial irritability, and blood pressure alterations. Blood pressure initially rises and then gradually falls. Changes in the cardiovascular status are accompanied by electrocardiographic changes. First, there is sinus bradycardia, then T wave inversion, and finally the development of a J wave [10]. At core temperatures below 28°C, ventricular fibrillation is a major threat to life.

Despite its gravity, the management of the hypothermia of myxedema coma differs from the treatment of exposure-induced hypothermia in
euthyroid subjects. In myxedema coma, the patient should be kept in a warm room and covered with blankets. Active rewarming should be avoided, because it increases oxygen consumption and promotes peripheral vasodilation and circulatory collapse. Active rewarming is recommended only for situations of severe hypothermia in which ventricular fibrillation is an immediate threat.

**Hypotension**

Hypotension is another ominous feature of myxedema coma. Hypothermia and thyroid hormone deficiency per se are the two most important causes of hypotension, but bleeding and, perhaps in some cases, decreased adrenal reserve may also play a role. Because hypothermia itself produces hypotension, some improvement in blood pressure can be expected if passive measures to restore body temperature are successful. Intravenous fluids should be administered carefully as patients undergo rewarming. Anemia is common in hypothyroidism and has a multifactorial basis. In patients in whom anemia is severe or there appears to be active bleeding, a case can be made for transfusion. If this course is chosen, it must be done with great caution because patients with myxedema coma are extremely prone to circulatory collapse. Sympathomimetic vasoconstrictors or inotropic agents have very limited use in myxedema coma. The response to these drugs is poor, and myxedematous patients are very sensitive to their toxic effects.

**Glucocorticoid Therapy**

Although there is little evidence that hypotension in myxedema coma results from adrenal insufficiency, there are at least theoretical reasons for considering that these patients have decreased adrenal reserve. Furthermore, it is sometimes unclear whether the myxedema coma is due to primary or pituitary-hypothalamic hypothyroidism. Therefore, one of the immediate measures in treating myxedema coma is to administer 300 mg hydrocortisone intravenously in three divided doses during the first 24 hours. Gradually decreasing doses of hydrocortisone should be administered over the next few days, depending on the patient’s response, or until adrenal insufficiency has been excluded. This protocol is recommended even in the absence of hypotension.

**Sepsis**

Infections, especially pneumonia and urosepsis, are precipitants or comorbidities in up to 80% of patients with myxedema coma, and sepsis is an important cause of death for these patients [2,4,6–8]. Some signs of
sepsis such as tachycardia and fever may be absent in the initial presentation of patients with myxedema. A careful evaluation for underlying infections should be conducted for each patient. When suspected, such infections should be treated aggressively. The management of sepsis is discussed in detail in Chapter 39.

Thyroid Hormone

Administration of thyroid hormone is the definitive treatment of myxedema coma and is essential for reversing hypotension, hypothermia, and depressed consciousness. The sensorium may be improved for a few patients when glucose is given or hypoventilation corrected, but deterioration recurs if thyroid hormone is not given. The gastrointestinal absorption of thyroid hormone is often markedly reduced in myxedema coma. Therefore, thyroid hormone must be given by the intravenous route. To ensure proper dosing, synthetic preparations should be used.

There are no large controlled studies of the optimum form of thyroid hormone for myxedema coma or, for that matter, any aspect of the treatment of myxedema coma. Both T4 and T3 have been used with varying degrees of success, and each has its theoretical advantages. T4 is advantageous because most thyroid hormone is secreted in the form of T4. For this and other reasons, plasma and intracellular T4 and T3 profiles are more stable and representative of the normal condition if T4 rather than T3 is administered. Conversely, T3 is advantageous because it has a more rapid onset of action than T4.

The best doses for treating myxedema coma have not been studied in a rigorous fashion. As is the case when deciding between T4 and T3, the choice is not straightforward. In patients with long-standing untreated hypothyroidism, thyroid hormone treatment is usually initiated at low doses. These patients frequently have underlying arteriosclerotic cardiovascular disease, and initial therapy with full replacement doses of thyroid hormone can precipitate angina or myocardial infarction. On the other hand, in near-terminal patients with myxedema coma, the need for thyroid hormone is urgent. In this setting, the blood pressure and body temperature can increase within hours after thyroid hormone is started.

We and others [16] prefer T4 in all but the most severe cases of myxedema coma. Except in elderly patients, the initial intravenous dose
of $T_4$ should be between 0.2 and 0.4 mg, with the larger doses in this range used for more comatose patients, those with more severe hypotension or hypothermia, and those with large body mass. In the elderly patient or those with a history of heart disease, the initial $T_4$ dose should probably not exceed 0.4 mg. Doses exceeding 0.5 mg per day may be associated with higher mortality [6]. If there is no improvement in the state of consciousness, blood pressure, or core temperature in the first 6 to 12 hours after the initial dose, $T_4$ should again be administered to bring the total dose during the first 24 hours to 0.4 mg. Thyroid hormone should then be given again 24 hours later and every 24 hours thereafter. After the first 24 hours, the subsequent doses should range from 0.05 to 0.2 mg daily, depending on the clinical response. If the treatment is not maintained, coma may recur. One prospective study randomly assigned 11 patients to two groups: one received a loading dose of 0.5 mg of $T_4$ intravenously followed by a daily maintenance dose of 0.1 mg intravenously (“high-dose” group); the other group received only the maintenance dose of 0.1 mg daily (“low-dose” group). Four of eleven patients died, but only one of them was in the “high-dose” group. The mortality rate was lower in the “high-dose” group, but did not reach statistical significance. However, the sample size was small. Based on this information, it was suggested that patients who receive a loading dose fared better than those on less vigorous regimens [8]. A smaller dose in comatose patients is probably indicated in very elderly patients [6], or in patients who are normotensive and euthermic and have another explanation for their comatose state, such as CNS trauma or recent sedative ingestion. Another situation that calls for lower doses is the patient who has had an acute myocardial infarction and whose hypotension appears to be secondary to the myocardial infarction, which is a major contributor to the patient’s depressed sensorium. In these cases, ventilatory support should be given and intravenous doses of as little as 0.05 to 0.1 mg of $T_4$ administered in the first 24 hours. Care must be taken when making the diagnosis of myocardial infarction, however, since creatine kinase-MB activity is increased in the absence of myocardial infarction in a few patients with myxedema coma [17,18]. Troponin levels are more specific markers of cardiac injury, and are probably affected to a lesser degree, although there have also been reports of troponin elevations in hypothyroidism in the absence of cardiac disease [19–23].

For severe cases of myxedema coma where there is a poor initial response to levothyroxine, addition of intravenous $T_3$ may be considered [16]. If $T_3$ is used, however, greater caution must be exercised to avoid overstimulation of the cardiovascular system [2] and too rapid an
increase in oxygen consumption. It is clear that T₃ has been lifesaving in some patients, but high doses of administered T₃ and high calculated plasma T₃ concentrations have also been associated with increased mortality [2,6]. Although doses as high as 0.2 mg of T₃ in the first 24 hours have been used, as little as 0.0025 mg has been reported to increase cardiac output, heart rate, ventricular stroke work, oxygen consumption, and oxygen delivery in myxedema coma [24]. Based on recent American Thyroid Association (ATA) recommendations, a loading dose 5 to 20 μg of T₃ can given intravenously, in addition to levothyroxine. This can be followed by a dose of 2.5 to 10 μg of T₃ every 8 hours [16]. If signs of myocardial ischemia develop, the dose of T₃ should be reduced. Particularly worrisome would be a decrease in blood pressure in the face of an increase in body temperature, suggesting that cardiovascular decompensation is occurring in the face of increased oxygen demands. If there is gradual improvement of metabolic parameters, the T₃ can be tapered and T₄ treatment continued. When the patient stabilizes and is fully conscious, T₄ can be given by the oral instead of the intravenous route. T₄ therapy must be closely monitored, however, as T₄ malabsorption can be a serious problem in a variety of clinical settings. If the clinical response to oral T₄ is not maintained or serum T₄ concentrations fall, the patient should be switched back to intravenous T₄ therapy.

Although myxedema coma is associated with a high mortality, many patients survive by using judicious therapy aimed at correcting the secondary metabolic disturbances and reversing the hypothyroid state. This must be done in a sustained but gradual fashion, however, because an effort to correct hypothyroidism too rapidly may completely negate the beneficial effects of the initial treatment.

Pertinent clinical studies of myxedema coma are listed in Table 142.3.

• Higher doses of T4 (≥0.5 mg/d) combined with T₃ (≥75 μg/d) have been associated with worse outcome. It is not known this association is due to patients with more severe forms of myxedema coma being treated with higher doses of thyroid hormone [2,6].

Nonthyroidal Illness Syndrome
(Sick Euthyroid Syndrome) in
the Intensive Care Unit

SHIRIN HADDADY • ALAN P. FARWELL

INTRODUCTION

Critical illness causes multiple alterations in thyroid hormone concentrations among patients who have no previously diagnosed intrinsic thyroid disease [1–8]. These effects are nonspecific and relate to the severity of the illness. The most common alterations of thyroid hormone parameters seen among these cases includes low triiodothyronine (T₃) levels, normal thyroid stimulating hormone (TSH) levels, and increased reverse triiodothyronine (rT₃) levels. Despite abnormalities of serum thyroid hormone parameters, there is little evidence that these patients have clinically significant thyroid dysfunction. The changes in serum thyroid function associated with a wide variety of acute illness have been termed “sick euthyroid syndrome,” “nonthyroidal illness syndrome,” or “low T₃ syndrome.” The changes in thyroid hormone parameters seen with the sick euthyroid syndrome are thought to be a response to systemic illness through a variety of different pathways. These changes are rarely isolated and often are associated with alterations in other endocrine systems, such as reductions in serum gonadotropin and sex hormone concentrations [9] and increases in serum corticotropin and cortisol levels [10]. Similar changes in endocrine function have been shown experimentally by the administration of cytokines from the interleukin (IL) and interferon families as well as tumor necrosis factor-α (TNF-α) [11]. One theory postulates that euthyroid sick syndrome may be a compensatory mechanism in response to the oxidative stress of acute illness. Thus, the sick euthyroid syndrome
should not be viewed as an isolated pathologic event but as part of a coordinated systemic reaction to illness that involves both the immune and endocrine systems.

The differentiation between patients with the sick euthyroid syndrome and those with intrinsic thyroid disease is a frequent diagnostic problem for intensive care unit (ICU) physicians. This chapter will first review normal thyroid physiology and discuss the changes in thyroid hormone metabolism seen with critical illness. Management of these patients and the identification of those with intrinsic thyroid disease will then be discussed. Finally, the use of thyroid hormone replacement in the sick euthyroid syndrome will be reviewed.
NORMAL THYROID HORMONE ECONOMY

Regulation

The synthesis and secretion of thyroid hormone is under the control of the anterior pituitary hormone, thyrotropin (TSH). In a classic negative feedback system, TSH secretion increases when serum thyroid hormone levels fall and decreases when they rise (Fig. 143.1). TSH secretion is also under the regulation of the hypothalamic hormone, thyrotropin-releasing hormone (TRH). The negative feedback of thyroid hormone is targeted mainly at the pituitary level but likely affects TRH release from the hypothalamus as well. In addition, input from higher cortical centers can affect hypothalamic TRH secretion.
Under the influence of TSH, the thyroid gland synthesizes and releases
thyroid hormone. Thyroxine (T₄, 65% iodine by weight) is the principal secretory product of the thyroid gland, comprising ~90% of secreted thyroid hormone under normal conditions [12]. Although T₄ may have direct actions in some tissues, T₄ primarily functions as a hormone precursor that is metabolized in peripheral tissues to the transcriptionally active 3,5,3′-triiodothyronine (T₃, 59% iodine by weight).

**Metabolic Pathways**

The major pathway of metabolism of T₄ is by sequential monodeiodination [13] (Fig. 143.2). At least three deiodinases, each with its unique expression in different organs, catalyze the deiodination reactions involved in the metabolism of T₄. Removal of the 5′-, or outer ring, iodine by type 1 iodothyronine 5′-deiodinase (type 1 deiodinase, D1) is the “activating” metabolic pathway, leading to the formation of T₃.

Removal of the inner ring, or 5-, iodine by type 3 iodothyronine deiodinase (type 3 deiodinase, D3) is the “inactivating” pathway, producing the metabolically inactive hormone, 3,3′,5′-triiodothyronine (reverse T₃, rT₃). Type 1 deiodinase (D1) is found most abundantly in the liver, kidneys, and thyroid. It is upregulated in hyperthyroidism and downregulated in hypothyroidism. Type 3 deiodinase is expressed primarily in the brain, in skin, and in placental and chorionic membranes. The actions of D3 also include the inactivation of T₃ to form T₂, another inactive metabolite. Under normal conditions, ~41% of T₄ is converted to T₃, ~38% is converted to rT₃, and ~21% is metabolized via other pathways, such as conjugation in the liver and excretion in the bile [4,5].

---

p. 1311

p. 1312
**FIGURE 143.2** Pathways of thyroid hormone metabolism. Thyroid hormones are metabolized by outer ring deiodination (1, type 1 and type 2 5’-deiodinase), inner ring deiodination (2, type 3 5-deiodinase), or by nondeiodinative pathways (3). Deiodination is the major route of T₄ metabolism in healthy individuals, and nondeiodinative pathways of metabolism assume a greater role in critically ill patients.

T₃ is the metabolically active thyroid hormone and exerts its actions via binding to chromatin-bound nuclear receptors and regulating gene transcription in responsive tissues [14]. Important for understanding of the alterations of circulating thyroid hormone levels seen with critical illness is the fact that only ~10% of circulating T₃ is secreted directly by the thyroid gland, whereas >80% of T₃ is derived from conversion of T₄ in peripheral tissues [12,13]. Thus, factors that affect peripheral T₄ to T₃ conversion will have significant effects on circulating T₃ levels. Serum
levels of T₃ are approximately 100-fold less than those of T₄, and, like T₄, T₃ is metabolized by deiodination to form diiodothyronine (T₂) and by conjugation in the liver. The half-lives of circulating T₄ and T₃ are 5 to 8 days and 1.3 to 3 days, respectively [15].

Serum-Binding Proteins

Both T₄ and T₃ circulate in the serum as bound hormones to several proteins synthesized by the liver [16]. Thyroxine-binding globulin (TBG) is the predominant transport protein and binds ~80% of the circulating serum thyroid hormones. The affinity of T₄ for TBG is approximately 10-fold greater than that of T₃ and is part of the reason that circulating T₄ levels are higher than T₃ levels. Other serum-binding proteins include transthyretin [17], which binds ~15% of T₄ but little, if any, T₃, and albumin, which has a low affinity but a very large binding capacity for T₄ and T₃. Overall, 99.97% of circulating T₄ and 99.7% of circulating T₃ is bound to plasma proteins.

Free Hormone Concept

Essential to the understanding of the regulation of thyroid function and the alterations of circulating thyroid hormones seen with critical illness is the “free hormone” concept, which is that only the unbound hormone has any metabolic activity. Under the regulation by the pituitary, overall thyroid function is affected when there are any changes in free hormone concentrations. Changes in either the concentrations of binding proteins or the binding affinity of thyroid hormone to the serum-binding proteins have significant effects on the total serum hormone levels because of the high degree of binding of T₄ and T₃ to these proteins. Despite these changes, this does not necessarily translate into thyroid dysfunction.
THYROID HORMONE ECONOMY WITH CRITICAL ILLNESS

The widespread changes in thyroid hormone economy of the critically ill patient occurs as a result of: (a) alterations of the peripheral metabolism of the thyroid hormones, (b) alterations of TSH regulation, (c) alterations of the binding of thyroid hormone to TBG, (d) alterations of thyroid hormone transporters, and (e) alterations of nuclear thyroid hormone receptors [7].

Alterations of Metabolic Pathways

The acute decrease in T₃ and increase in rT₃ early in the euthyroid sick syndrome initially was thought to result solely from the acute inhibition of D₁ in liver and kidneys by a variety of factors (Table 143.1) [13]. However, increased D₃ activity in liver and inflammatory cells has been reported in both animal models of tissue injury and hospitalized patients with acute illnesses [18]. Studies of human tissues obtained from patients who died during acute illness showed a decrease in D₁ activity and an increase in D₃ activity, whereas there was no change or absent D₂ activities in liver and skeletal muscles [19–21]. In addition, increases in nondeiodinative pathways such as sulfoconjugation [22] and alanine side chain deamination/decarboxylation [1] have been reported to be increased with the euthyroid sick syndrome. Thus, it has become clear that there are many pathways that all serve to drive down T₃ levels early in the euthyroid sick syndrome.

An extensive review of thyroid hormone metabolism with inflammation and infection by Boelen et al. [23] described different alterations of deiodinase activity in different tissues during acute illness, as summarized in Table 143.2. In a rodent model of acute inflammation, liver D1 expression is decreased, presumably as a result of regulation through thyroid hormone receptor β1 (TRβ1) [23]. Changes in deiodinase expression have also been seen in a pig model of septic shock induced by bacterial endotoxin, lipopolysaccharide (LPS), with decreases in liver and kidney D1 expression and activity and increases in hypothalamic, thyroidal, and liver D3 activity [24].

Humans—bacterial sepsis No change in D1 or D3 activities

In the hypothalamus, D2 is thought to be the major contributor of hypothalamic T₃ production. In the rodent model of acute illness, there is an increase in D2 mRNA expression and activity seen in the hypothalamus [25], which is also seen in the mouse model of chronic inflammation [8,23] and among rabbits with chronic illness [26]. The mechanism of this increase of D2 expression and activity is unclear at this time, but it appears independent of change in serum T₃ levels, and the activation of nuclear factor-κB pathway may be involved [23]. On the other hand, hypothalamic D3 activity is unaltered among rabbits with chronic illness [26] and decreased for mice models of both acute and chronic inflammation [23]. The subsequent increase in local hypothalamic T₃ levels may contribute to the decrease in hypothalamic TRH mRNA expression seen with acute illness.

Data from the deiodinase knockout mice model have raised questions regarding the clinical significance of the changes in deiodinase activity with the euthyroid sick syndrome. The illness-induced changes in serum T₄ and T₃ levels were not significantly different between wild-type and TRβ1 knockout mice, despite differences seen for liver D1 mRNA expression and activity [27]. Similar findings were reported for alterations of liver D3 expression and activity in mouse models [23]. The relative lack of effects of changes in deiodinase expression and activity on serum thyroid hormone levels have also been shown in various deiodinase knockout mice models, as serum T₃ appears preserved even though rT₃ levels are undetectable [27,28].

Alterations of Thyroid Stimulating Hormone Secretion

Serum TSH levels usually remain normal during early phases of acute illness. However, with illness progression, TSH steadily decreases as a result of multiple factors (Table 143.3). These include several medications used for treatment of critical illness, such as dopamine and glucocorticoids, that have a direct inhibitory effect on TSH secretion.
Elevated endogenous cortisol also plays a role in suppressing TSH, especially during fasting and undernutrition [31]. In addition, D2 activity has been reported to be increased in the pituitary with the euthyroid sick syndrome, increasing local production of T₃ and decreasing TSH synthesis [32–34]. Further, increased production of thyroid hormone metabolites such as 3,5,3′-triiodothyroacetic acid (Triac) during acute illnesses also has a direct inhibitory effect on TSH synthesis.

TSH, thyroid stimulating hormone.

There is ample evidence of decreased TRH production and secretion leading to a decrease in TSH in the euthyroid sick syndrome [1,23]. Leptin, a hormone encoded by the ob gene and secreted by adipocytes, plays a role in balancing energy intake and expenditure. Leptin has been reported to directly regulate TRH production, and leptin and TSH levels are directly related [35,36]. Serum leptin levels decrease during fasting as well as among elderly patients with the euthyroid sick syndrome, leading
to subsequent decreases in TSH levels [37]. These changes likely serve as an adaptive mechanism to reduce catabolic process and energy expenditure in the setting of acute illness [37–39]. Increased hypothalamic D2 activity as well as increased Triac production also has been reported to directly decrease TSH production, similar to that observed in the pituitary [23].

Some investigators have hypothesized a central role for decreased TRH production in the euthyroid sick syndrome [40]. Further, TRH therapy has been postulated as a therapeutic intervention. Indeed, a trial of exogenous TRH administration in conjunction with growth hormone-releasing petide-2 in 14 patients with prolonged critical illness has been shown to restore the alterations seen in serum thyroid hormone parameters, with subsequent improvement for some of the cardiometabolic parameters such as protein degradation [40].

Alterations of Serum Thyroid Hormone-Binding Proteins

The majority of thyroid hormone is bound to various binding proteins in plasma, primarily TBG as well as transthyretin and albumin. As both acute and prolonged illness are typically accompanied by malnutrition and high catabolic state, serum levels of binding protein are frequently reduced [16]. A rapid decrease in TBG levels has also been seen among postcardiac bypass patients, which may also contribute to the decrease in serum T3 shortly after cardiac surgery [41].

In addition to decreases in the serum levels of binding proteins, binding of T4 to TBG is frequently decreased by a variety of factors present with critical illness (Table 143.4) [1]. Certain medications (heparin, furosemide, anti-seizure medications, salicylates) have been implicated in this decrease in binding. In addition, a factor that has the characteristics of unsaturated nonesterified fatty acids has been reported to interfere with TBG binding as well as inhibit T4 to T3 conversion [8] and block transport of T4 into tissue in the euthyroid sick syndrome [8,42,43].

Thyroid hormones are transported across the plasma membrane by specific thyroid hormone transporters, most notably those of the monocarboxylate transporter (MCT) and organic anion-transporting polypeptide (OATP) families [44,45]. Of these, MCT8, MCT10, and OATP1C1 have been extensively studied. OATP1C1 has been characterized in rat brain and found to have significant action for transporting T₄ across the blood–brain barrier. It is also found to be regulated, in part, by thyroid hormone levels in the brain [46]. MCT8 is found in cortical regions, striatum, cerebellum, and hypothalamus, and transports both T₄ and T₃, whereas MCT10 preferentially transports T₃ and is expressed in liver, kidney, and muscle [45,47].

There is impaired transport of T₄ into peripheral tissues such as liver and kidney seen with the euthyroid sick syndrome and with starvation, thereby decreasing the availability of substrate for T₃ production in these tissues [48]. Consistent with these observations, liver and muscle MCT8 mRNA expression is decreased among patients with acute illness or acute surgical stress, although MCT10 mRNA expression was not affected. However, there are conflicting data from animal studies showing increased OATP1C1 and MCT10 mRNA expression, while MCT8 mRNA expression did not change in a rabbit model of prolonged illness, contrary to what would be expected given findings seen with the euthyroid sick syndrome and starvation [26]. On the other hand, a more recent study using a pig model of septic shock showed decreases in pituitary, liver, and kidney MCT8 expression [24]. Further studies are needed to better
elucidate the underlying mechanisms of altered thyroid hormone transport with the euthyroid sick syndrome.

Alterations of Nuclear Thyroid Hormone Receptors

Thyroid hormone activity is mediated by binding to TRs, with two main isoforms: TRα and TRβ. TRs are ligand-bound transcription factors that regulate transcription of a variety of target genes in various tissues [49]. Concentrations of the receptor isoforms vary by tissues, with TRα predominating in brain, TRβ in liver, and both in cardiac muscles. Animal studies have shown conflicting data regarding changes in TRs with the euthyroid sick syndrome. In a mouse model of acute illness induced by bacterial endotoxin, LPS, a rapid decrease in mRNA for both TRα and TRβ as well as coactivator expression was seen in cardiac tissue [50]. This decrease in TRβ mRNA expression was also seen in heart, liver, and kidney with a LPS-induced pig model of acute septic shock [24]. On the other hand, there was no significant change in the levels of either TRα or TRβ among rabbits in a prolonged illness model [26]. Human studies of patients with liver and renal failure showed increased TRα and TRβ expression in mononuclear cells [51]. These findings were different from that seen for humans with chronic liver disease, where no change in TR expression in hepatic tissues was seen [23]. Meanwhile, adipose tissue from patients with septic shock showed decreased levels of transcription factors for TRβ1, with no significant change in expression for TRα1 and other coactivators or corepressors [23]. The mechanisms for these alterations in TRs remain unclear.

Role of Cytokines for the Pathogenesis of the Sick Euthyroid Syndrome

Cytokines are medium-sized polypeptide hormones secreted by mononuclear cells of the lymphoid system in response to a variety of stimuli, including infection by foreign organisms, invasion by foreign cells, metabolic derangements, and organ system dysfunction [52]. Cytokines have an array of systemic and local actions characteristic of illness, such as fever, prostration, inflammation, and the initiation of wound repair. Cytokine production by lymphoid cells is essential for the development and maintenance of immunity. The actions of cytokines include both autocrine and paracrine effects on cell proliferation and differentiation and on induction of other cytokines. Classes of cytokines include the ILs (1 to 12), interferons (α, β, and γ), TNFs (α and β), and
other assorted growth factors. Of these cytokines, TNF-α and several ILs (IL-1, 6, and 10) have been extensively studied for their role in the pathogenesis of the sick euthyroid syndrome [5,11, 53].

TNF-α, IL-1, and IL-6 concentrations are increased with systemic illness and are implicated as mediators of endotoxemia-induced shock, fever, and metabolic acidosis. TNF-α and IL-1 both induce the production of IL-6 and TNF-α also induces IL-1 production [54] and activates nuclear factor-kappa B (NF-κB), which has been shown to inhibit hepatic type 1 5′-deiodinase activity [55]. Serum concentrations of these cytokines have shown to be inversely proportional to serum T₃ concentrations in children (IL-6 and TNF-α [56]); postoperative patients (IL-6 [57]); hospitalized patients, including those with acute myocardial infarction (IL-6 [58–60]); after bone marrow transplantation (IL-6 and TNF-α [61]); and among nursing home patients (TNF-α [62]). However, there have been reports of a lack of correlation between IL-6 and TNF-α after abdominal surgery [63] and with rheumatoid arthritis [64]. The administration of cytokines to animals produces an acute fall in serum T₃ concentrations among rats (TNF-α [65], IL-1 [66,67], IL-6 [68]) and mice (IL-1 [69,70], IL-6 [71]) and shows a direct inhibitory effect on thyroid cells in culture (TNF-α [65,72,73] and IL-1 [73–75]). Variable effects on deiodinase enzymes have been reported, including an inhibition of type 1 5′-deiodinase (IL-1β [76], NF-κB [55]) and inhibition (TNF-α, IL-1, and IL-6 [77]) and induction of type 2 5′-deiodinase (response to LPS [32]).

The administration of TNF-α [78] or IL-6 [79] to healthy human volunteers as well as isolated limb perfusion of cancer patients with TNF-α [80] also produced an acute decrease in both serum T₃ and TSH concentrations and a rise in serum rT₃ concentrations, whereas the administration of an IL-1α receptor antagonist failed to alter the decrease in serum thyroid hormone concentrations observed after infusion of endotoxin in healthy males [81]. In addition, recovery from these changes in thyroid hormone parameters was associated with a rise in TSH [80], similar to the recovery phase of the sick euthyroid syndrome (see later).

Other cytokines have been variably investigated as to their role in the pathogenesis of the sick euthyroid syndrome. Interferon α causes a decrease in serum T₃ and TSH and a rise in serum rT₃ concentrations in both humans [82] and mice [74], and has been shown to directly inhibit thyroidal type 1 5′-deiodinase activity [72,73], whereas interferon γ appears to have no effect on thyroid hormone parameters [83]. An increase in TSH has been observed among patients treated with IL-2 [84]. Soluble cytokine receptors may play a regulatory role for the cytokine cascade by functioning as either carrier proteins or cytokine inhibitors [52,54], and serum T₃ levels were found to be inversely proportional to soluble receptors for TNF-α, IL-1, and IL-2 among
hospitalized patients [74].

Oxidative stress, whether or not mediated via cytokines, also may play a role in the development of the sick euthyroid syndrome. N-acetylcysteine (a potent intracellular antioxidant) administration to patients with acute myocardial infarction has been shown to prevent changes in T3 and rT3 seen during the acute phase of sick euthyroid syndrome, without altering the increased levels of IL-6 [85]. This observation may hint that oxidative stress due to increased reactive oxygen species seen with many disorders may play a role in disruption of deiodinases.

From the data discussed earlier, it is likely that cytokines play a role in the alterations of thyroid hormone metabolism that occur during systemic illness. Although all cytokines examined to date can produce the sick euthyroid syndrome in either humans or rodents when administered at pharmacologic doses, no one cytokine can be singled out as the primary mediator of the syndrome. This is not unexpected, given the diverse interrelationships and cascade nature of the cytokine network. Whether the sick euthyroid syndrome results from activation of the cytokine network or simply represents an endocrine response to systemic illness resulting from the same mediators that trigger the cytokine cascade remains to be determined.

**Stages of the Sick Euthyroid Syndrome**

As discussed earlier, critical illness causes multiple nonspecific alterations of thyroid hormone concentrations among patients without intrinsic thyroid dysfunction that relate to the severity of the illness [3, 86, 87]. One author has postulated that sick euthyroid syndrome may be a compensatory mechanism in response to the oxidative stress of acute illness [88]. Irrespective of the underlying cause, these alterations of thyroid hormone parameters represent a continuum of changes that depend on the severity of the illness and that can be categorized into several distinct stages (Fig. 143.3) [1]. The wide spectrum of changes observed often results from the differing points in the course of the illness that the thyroid function tests were obtained. Importantly, these changes are rarely isolated and often associated with alterations of other endocrine systems, such as decreases in serum gonadotropin and sex hormone concentrations [89] and increases in serum adrenocorticotropic hormone and cortisol levels [90]. Thus, the sick euthyroid syndrome should not be viewed as an isolated pathologic event but as part of a coordinated systemic reaction to illness involving both the immune and endocrine systems.
Alterations in thyroid hormone concentrations with critical illness. Schematic representation of the continuum of changes in serum thyroid hormone levels in patients with nonthyroidal illness. These alterations become more pronounced with increasing severity of the illness and return to the normal range as the illness subsides and the patient recovers. A rapidly rising mortality accompanies the fall in total and free T₄ levels.

Low T₃ State

Common to all of the abnormalities of thyroid hormone concentrations seen among critically ill patients is a substantial depression of serum T₃ levels, which can occur as early as 24 hours after the onset of illness. Over half of the patients admitted to the medical service will demonstrate depressed serum T₃ concentrations [91,92]. The development of the low T₃ state arises from the impairment of peripheral T₄ to T₃ conversion through the inhibition of type 1 deiodinase (discussed earlier). This results in the marked reduction in T₃ production and rT₃ degradation [93], thereby leading to the reciprocal changes in serum T₃ and serum rT₃ concentrations. Low T₃ levels are also found in the peripheral tissues [19]. Previously, it was thought that the inhibition of type 1 deiodinase was the sole cause of the low T₃ syndrome by decreasing T₃ production. Recent studies suggest that increased type 3 deiodinase with critical illness increases T₃ disposal, adding to the decrease in serum T₃ levels [18,19]. TR expression is also decreased with acute nonthyroidal illnesses [94], possibly in response to the decrease in tissue T₃ levels.

High T₄ State
Serum T₄ levels may be elevated early in acute illness because of either the acute inhibition of type 1 deiodinase or increased TBG levels. This is seen most often among the elderly and among patients with psychiatric disorders. As the duration of illness increases, nondeiodinative pathways of T₄ degradation increase serum T₄ levels to the normal range [91].

**Low T₄ State**

As the severity and the duration of the illness increase, serum total T₄ levels decrease into the subnormal range. Contributors to this decrease in serum T₄ levels are (a) a decrease in the binding of T₄ to serum carrier proteins, (b) a decrease in serum TSH levels leading to decreased thyroidal production of T₄, and (c) an increase in nondeiodinative pathways of T₄ metabolism. The decline of serum T₄ levels correlates with prognosis in the ICU, with mortality increasing as serum T₄ levels drop below 4 μg per dL and approaching 80% for patients with serum T₄ levels below 2 μg per dL [95–97]. Despite marked decreases in serum total T₄ and T₃ levels among critically ill patients, their free hormone levels have been reported to be normal or even elevated [98,99], providing a possible explanation for why most patients appear euthyroid despite thyroid hormone levels in the hypothyroid range. Thus, the low T₄ state is unlikely to be a result of a hormone-deficient state and is probably more of a marker of multisystem failure of these critically ill patients.

**Recovery State**

As acute illness resolves, so do the alterations in thyroid hormone concentrations. This stage may be prolonged and is characterized by modest increases in serum TSH levels [100]. Full recovery, with restoration of thyroid hormone levels to the normal range, may require several weeks [101] or months after hospital discharge [92]. One study reported that 35 of 40 patients with nonthyroidal illness after coronary artery bypass grafting (CABG) were able to regain normal thyroid function within 6 months after surgery [102].
ALTERATIONS OF THYROID FUNCTION IN SPECIFIC CRITICAL ILLNESSES

Caloric Deprivation

Most, if not all, nonthyroidal illness is associated with decreased caloric intake, catabolism, and/or malnutrition. Caloric deprivation is the most common inhibitory factor of type 1 5′-deiodinase \([13,103,104]\). Serum T₃ levels decrease and rT₃ levels increase within 24 hours of the onset of a fast. The decrease in serum T₃ levels may possibly be an adaptive response in order to preserve the total body protein stores. Indeed, restoring the serum T₃ to normal during starvation results in a marked increase in urinary nitrogen excretion \([105]\). Thus, the inhibition of T₄ to T₃ conversion during starvation can be viewed as a condition of adaptive hypothyroidism. Further support for the role of caloric deprivation during the development of the sick euthyroid syndrome is the demonstration that early nutritional support for postoperative patients can prevent development of the euthyroid sick syndrome \([106]\). On the other hand, early feeding within 24 hours of hospitalized burn patients with evidence of the euthyroid sick syndrome, compared to delayed feeding after more than 48 hours, was associated with prevention of the euthyroid sick syndrome development as well as decreased length of stay (Table 143.5) \([107]\). Recently, a large randomized clinical trial suggested that parenteral nutrition postponed to 1 week after ICU admission had beneficial effects on the rates of complications as well as timing of recovery \([108]\). Comparison of critically ill patients who received early parenteral nutrition to patients who received parenteral nutrition after 1 week showed a lower level of T₃ and T₃/rT₃ and a higher level of rT₃ in the latter group.

TABLE 143.5 Summary of Clinical Trials on the Effects of Treatment of the Sick Euthyroid Syndrome with Thyroid Hormone
Starvation/undernutrition

Treatment with T₃ results in increased protein breakdown and increased nitrogen excretion in fasting normal and obese patients [105,195,196].

General intensive care unit patients

No benefit of L-T₄ on general medical patients [140], patients with acute renal failure [141], or those undergoing renal transplantation [142]. No benefit of T₃ in burn patients [143].

Premature infants

No benefit of L-T₄ on developmental indices of premature infants at 26–28 wk’s gestation [155]. Possible beneficial effect of L-T₄ on infants of 25–26 wk’s gestation but possible deleterious effects on infants of 27–30 wk’s gestation [156]. No benefit of T₃ [160]. Meta-analysis shows no significant effects of thyroid hormone treatment in premature infants [161].

Patients undergoing cardiac surgical procedures

Small studies suggest improved hemodynamic variables with T₃ [171,172]. Large trials show no benefit of T₃ in patients undergoing cardiac bypass [173,175,197]. Possible improvement in hemodynamic variables and hospital stay with T₃ in children undergoing cardiac surgical procedures [176,177].

Cardiac donors

Variable results—helpful [179,180], no benefit [178,181]—of the effects of T₃ in preserving function of normal hearts in brain dead cardiac donors before transplantation. Possible benefits of T₃ in improving function of impaired hearts before transplantation, potentially increasing the pool of organs available for transplantation [178,182]. Consensus conferences recommend the use of T₃ as part of the hormonal resuscitation in donors whose cardiac ejection fraction is <45% [180].

Congestive heart failure

Small uncontrolled study suggested that short-term L-T₄ therapy increased cardiac output and functional capacity and decreased systemic vascular resistance [189]. Improved hemodynamic variables and neurohumoral profiles with short-term
intravenous T₃ infusion, possibly necessitating supraphysiologic concentrations [190,191]

T₃, triiodothyronine; L-T₄, levothyroxine.

HIV Infection

A unique pattern of changes in circulating thyroid hormone levels is seen among patients with human immunodeficiency virus (HIV) infection and in those with acquired immune deficiency syndrome (AIDS) [109]. A progressive increase in TBG levels is commonly observed, and T₄ levels rarely decrease below the normal range. Serum rT₃ levels fail to rise with advancing infections and are only modestly increased in preterminal AIDS patients. Most striking is the observation that serum T₃ levels remain in the normal range despite progression of the HIV infection and are only mildly decreased among critically ill AIDS patients, suggesting that these “inappropriately normal” T₃ levels play a role in the wasting and weight loss seen in the terminal phases of this disease. In contrast to T₄ levels of the sick euthyroid syndrome, it is the decreased serum T₃ levels in AIDS patients admitted to the ICU with Pneumocystis jirovecii infections that correlates with increased mortality [110].

Liver Disease

In contrast to the decrease in thyroid hormone levels seen in critically ill patients, individuals suffering from acute and chronic hepatocellular dysfunction often have marked elevations of total T₄ levels similar to those seen in patients with thyrotoxicosis [111]. T₃ levels are also higher than expected with illness and tend to fall late in the course of terminal liver disease. The etiology of these increased thyroid hormone concentrations is the increased discharge of TBG following destruction of hepatocytes. Free hormone measurements remain in the normal range. As with other illnesses, the low T₄ syndrome can be seen among patients with cirrhosis and is associated with increased mortality [112].

Cardiac Disease

Thyroid hormones have profound effects on the cardiovascular system [113]. Cardiac contractility, systolic time intervals, and heart rate are all increased in thyrotoxicosis and decreased in hypothyroidism. Multiple cardiac genes are either positively or negatively altered by thyroid
hormone\cite{114,115}. Serum T\textsubscript{4} and T\textsubscript{3} levels fall acutely following myocardial infarction\cite{116}, cardiac arrest\cite{117–119}, and CABG with and without cardiopulmonary bypass\cite{102,120–123}. A significant inverse relationship between free T\textsubscript{3} and global oxygen consumption has been demonstrated after CABG with and without cardiopulmonary bypass\cite{123}. Nonthyroidal illness syndrome has also been found with a prevalence of 62.2\% among patients with stress cardiomyopathy\cite{124}. In contrast to other medical illnesses where serum T\textsubscript{4} levels are correlated with prognosis, serum T\textsubscript{3} concentrations are a negative prognostic factor for patients with congestive heart failure\cite{125,126} and with coronary artery disease\cite{127}, raising a question as to what, if any, role thyroid hormones play in acute cardiac injury.
MANAGEMENT OF THE CRITICALLY ILL PATIENT WITH ABNORMAL THYROID FUNCTION TESTS

Evaluation

The identification of the critically ill patient with intrinsic thyroid disease is often difficult and always a diagnostic challenge. The routine screening of an ICU population for the presence of thyroid dysfunction is not recommended because of the high prevalence of abnormal thyroid function tests and low prevalence of true thyroid dysfunction. Whenever possible, it is best to defer evaluation of the thyroid–pituitary axis until the patient has recovered from his or her acute illness. In principle, when thyroid function tests are ordered for a hospitalized patient, it should be with a high clinical index of suspicion for the presence of thyroid dysfunction. For example, thyroid function should be evaluated for the patient admitted to the ICU with tachyarrhythmias when that patient also has a goiter, proptosis, and a tremor. Similarly, the patient with a large pericardial effusion, hypothermia, a goiter, and “hung-up” deep tendon reflexes should suggest the diagnosis of hypothyroidism. In practice, however, thyroid function tests are ordered in the patient with less-specific clinical findings and often present a diagnostic dilemma. Because every test of thyroid hormone function can be altered in the critically ill patient, no single test can definitively rule in or rule out the presence of intrinsic thyroid dysfunction.

Primary Tests

Sensitive Thyrotropin Assays

The development of the sensitive TSH assay has both helped and hindered the evaluation of thyroid function among the critically ill. These new assays have greatly expanded the lower range of the TSH assay, so the typical sensitive TSH assay has a lower limit of detection of 0.01 to 0.03 mU per L, which is 20- to 30-fold lower than the lower limit of the normal range. With this improved sensitivity has come the recognition of an increased frequency of subnormal TSH values among hospitalized patients, indicating that transient abnormalities of TSH secretion are commonplace among those with acute illness. To what degree this TSH
dysregulation represents clinically significant alterations of thyroid function is uncertain.

Abnormal thyroid function tests have been reported in 20% to 40% of acutely ill patients, of which >80% have no intrinsic thyroid dysfunction after the resolution of the illness [91,92,128]. In a study of 1,580 hospitalized patients, only 24% of patients with suppressed TSH values (TSH < assay limit of detection) and 50% of patients with TSH values >20 mU per L were found to have thyroid disease [91,92]. More importantly, none of the patients with subnormal but detectable TSH values and only 14% of patients with elevated TSH values <20 mU per L were subsequently diagnosed with intrinsic thyroid dysfunction. The development of sensitive third-generation TSH assays has led to small improvements in discerning between overt hyperthyroidism and nonthyroidal illness [92]. Overall, however, while a normal TSH level has a high predictive value for normal thyroid function, an abnormal TSH value alone is not helpful for the evaluation of thyroid function in the critically ill patient.

**Serum T4 Assays**

Measurement of free thyroid hormone concentrations in the patient with nonthyroidal illness is fraught with difficulty [99]. The gold standard of the determination of free hormone levels is by equilibrium dialysis. However, this technique is labor intensive and time consuming and, thus, is rarely used. The most commonly available laboratory tests of thyroid hormone concentrations, the free T4 index, free T4, and free T3, are measured by analog methods, which represent estimates of the free hormone concentration and are therefore subject to inaccuracies [98].

The free T4 index is determined by multiplying the total T4 concentration by the T3- or T4-resin uptake, which is an inverse estimate of serum TBG concentrations [129]. Recent developments have allowed the measurement of free T4 levels by the analog method, a less expensive alternative to the free T4 index [130], but the two tests are likely comparably accurate [131]. In a healthy population, there is a close correlation between the free T4 index and free T4 levels. Among critically ill patients, this association is no longer seen, mainly due to difficulties in estimating TBG binding with resin uptake tests. In spite of this, the sensitivity of the free T4 index in a large study of hospitalized patients was 92.3%, as compared to 90.7% for the sensitive TSH test [92].

**Secondary Tests**
Serum T₃ and rT₃ Assays

As previously discussed, serum T₃ concentrations are affected to the greatest degree by the alterations in thyroid hormone economy resulting from acute illness. Therefore, there is no indication for the routine measurement of serum T₃ levels in the initial evaluation of thyroid function in the critically ill patient. This test should only be obtained if thyrotoxicosis is clinically suspected in the presence of a suppressed sensitive TSH value and an elevated or high normal free T₄ index or free T₄ determination. Thus, in patients with an elevated free T₄ index or free T₄ and a suppressed TSH, the finding of an elevated serum T₃ concentration will differentiate between thyrotoxicosis and the high T₄ state of the sick euthyroid syndrome. The total T₃ assay is preferable to the free T₃ (analog) assay because of the variability between laboratories with the latter test [129].

Although some investigators have reported that serum rT₃ levels are a significant prognostic indicator of mortality in the ICU [132], rT₃ levels are generally unreliable and should not be used to distinguish between intrinsic thyroid dysfunction and nonthyroidal illness [133].

Serum Thyroid Autoantibodies

Autoantibodies to thyroglobulin and thyroid peroxidase, two intrinsic thyroid proteins, are commonly ordered tests [129]. Although significant titers of either or both of these antibodies indicate the presence of autoimmune thyroid disease, the presence of thyroid autoantibodies alone does not necessarily indicate thyroid dysfunction, as they are present among approximately 12% to 26% of the general population [134]. Thyroid autoantibodies do, however, add to the sensitivity of abnormal TSH and free thyroxine index values for diagnosing known intrinsic thyroid disease [91,92].

Imaging Studies

Imaging studies are rarely essential for the diagnosis of thyroid disorders of the critically ill patient. Occasionally, functional analysis of the thyroid gland using the radioisotope ¹²³I may be useful for the patient with suspected thyrotoxicosis and equivocal laboratory tests. However, these studies are labor intensive and the management of the underlying acute illness often overshadows the benefits of obtaining these studies.
Although anatomic studies such as ultrasound, isotopic imaging, computed tomography, and magnetic resonance imaging are useful in the evaluation of thyroid nodules and goiter, these conditions rarely are the cause of acute illness; as such, these studies are not usually helpful for the critically ill patient.

Diagnosis

As indicated, the diagnostic significance of a single abnormal thyroid function test is low. The best single test to screen for thyroid dysfunction is either the free $T_4$ index or the free $T_4$, realizing that subtle changes in thyroid function will be missed. However, a reasonable approach to the initial evaluation of the thyroid function in the critically ill patient is to obtain either free $T_4$ index or free $T_4$ and TSH measurements in patients with a high clinical suspicion for intrinsic thyroid dysfunction. Assessment of these values in the context of the duration, severity, and stage of illness of the patient will allow the correct diagnosis for most patients. For example, a mildly elevated TSH coupled with a low free $T_4$ index or free $T_4$ is more likely to indicate primary hypothyroidism early in an acute illness as opposed to the same values obtained during the recovery phase of the illness. Similarly, the combination of an elevated TSH and low normal free $T_4$ index or free $T_4$ is more likely to indicate thyroid dysfunction in the hypothermic, bradycardic patient than the tachycardic, normothermic individual. A rise in TSH during worsening stages of critical illness is likely to be due to thyroid hormone deficiency, so attention should be given to thyroid hormone replacement or titration of thyroid hormone dose in a patient who is already on treatment [135]. If both the free $T_4$ index or free $T_4$ and TSH are normal, thyroid dysfunction is effectively eliminated as a significant contributing factor to the clinical picture. If the diagnosis is still unclear, measurement of thyroid antibodies is helpful as a marker of intrinsic thyroid disease and increases the sensitivity of both the free $T_4$ index or free $T_4$ and the TSH. Only in the case of a suppressed TSH and a mid-to-high normal free $T_4$ index or free $T_4$ is measurement of serum $T_3$ levels indicated.

Prognosis

Both serum $T_4$ and serum $T_3$ concentrations have been associated as
negative indicators of prognosis when they are low. As mentioned previously, a direct relationship exists between low serum T₄ levels and poor outcomes among critically ill patients [128]. In acutely ill older patients with nonthyroidal illness syndrome, mortality rate was significantly higher, with an inverse relationship between free T₃ values and death rates [136]. The same relationship was found for burn patients, with free T₃ and TSH levels lower in non-survivors compared to survivors [137]. Among patients on mechanical ventilation, patients with low free T₃ had higher mortality rate and longer duration of mechanical ventilation and ICU length of stay [138]. Addition of free T₃ level to the APACHE II (Acute Physiology and Chronic Health Evaluation II) score has been suggested by some investigators to improve the ability to predict mortality of critically ill adults [139]. In different types of cardiac diseases the prognostic value of low T₃ has been shown, including coronary artery disease and chronic heart failure [125–127]. Whether this is a causal association or simply reflecting multiorgan failure is unclear.
TREATMENT OF THE SICK EUTHYROID SYNDROME WITH THYROID HORMONE

Thyroid Hormone Therapy of General ICU Patients

There are only a few studies examining the use of supplemental thyroid hormone therapy for the critically ill general medical patient. The initial study of medical ICU patients by Brent and Hershman examined the effect of thyroid hormone therapy for patients with serum T₄ levels <5 μg per dL but with no evidence of intrinsic thyroid dysfunction [140]. Either T₄ or placebo was given intravenously on a daily basis, with subsequent normalization of serum T₄ levels by day 5 in the T₄-treated group. There was no difference in mortality between the two groups and the elevation of TSH and serum T₃ concentrations seen during the recovery phase of acute illness was delayed for the T₄-treated group, suggesting that T₄ replacement was detrimental to the restoration of normal pituitary–thyroid regulation. A double-blind study with T₄ for patients with acute renal failure [141] showed that the mortality in the non–T₄-treated control group was significantly less than in the T₄-treated group; however, the mortality of the T₄-treated group was similar to that institution’s experience and in historical controls, so a specific deleterious effect of T₄ could not be proved. A follow-up double-blind study with T₄ for patients after renal transplantation by the same group [142] also failed to find any benefit.

One could argue that L-T₄ therapy for the sick euthyroid syndrome would be unlikely to have any effect because of the marked inhibition of T₄ to T₃ conversion, preventing significant increases in serum T₃ concentrations. Addressing this issue, Becker et al. [143] examined the effect of treatment with T₃ among 36 patients with acute burn injuries. Treatment with L-T₃ 200 μg daily in four divided doses orally normalized serum T₃ concentrations but resulted in no change in either mortality or basal metabolic rate. Thus, despite the poor prognosis of the general ICU patients with the sick euthyroid syndrome [128], it does not appear that treatment with either L-T₄ or L-T₃ provides significant benefit to these patients.
Thyroid Hormone Therapy in Premature Infants

Fetal thyroid function begins between 8 and 10 weeks’ gestation and continues to mature throughout pregnancy [144,145]. Serum T₄ concentrations remain low throughout most of the second trimester and then steadily increase, with a twofold rise occurring between 24 and 34 weeks, at which time serum T₄ levels plateau [146]. There has been a remarkable increase in the number of surviving premature infants, especially in those <30 weeks’ gestation. All premature infants have some degree of transient hypothyroxinemia, with serum T₄ concentrations varying directly with gestational age [147]. Approximately 50% of infants born <30 weeks’ gestation have serum T₄ concentrations <6.5 μg per dL [146,148,149]. Superimposed on this physiologic hypothyroxinemia often are concurrent illnesses such as respiratory distress syndrome, infections, and malnutrition that contribute to the development of the sick euthyroid syndrome. Severe hypothyroxinemia with concentrations <4 μg per dL were seen in 21% of preterm babies, ranging from 40% at 23 weeks’ gestation to 10.2% at 29 weeks [147]. Unlike adults, among whom most abnormalities resulting from clinical hypothyroxinemia are reversible, untreated congenital hypothyroxinemia can potentially have a devastating effect on brain development of the neonate [150-152].

Reuss et al. [153] showed that severe hypothyroxinemia of premature infants of <33 weeks’ gestation correlated with a fourfold increase in a diagnosis cerebral palsy. In the study with the longest follow-up, hypothyroxinemia in premature infants of <32 weeks’ gestation was associated with a 30% increase in school failure, poor school performance, and need for special education by 9 years of age [154].

The initial double-blind study of T₄ treatment of 23 premature infants of gestational age 26 to 28 weeks with hypothyroxinemia showed no differences between the groups in developmental indices at 1 year of age [155]. In the largest study to date, 200 infants born at 25 to 30 weeks’ gestation received either thyroxine or placebo for 6 weeks and neurologic development was assessed periodically up to 24 months [156]. Although there appeared to be a beneficial effect for thyroxine in the very young (25 to 26 weeks’ gestation), there also appeared to be a deleterious effect on the infants of 27 to 30 weeks’ gestation. This study group was reevaluated 3 years later at early school age and reported a trend toward a benefit of T₄ supplementation on IQ and behavioral issues at 24/25 weeks’
gestation but a significant deleterious effect on IQ and no effect on behavioral issues in those treated at 29 weeks’ gestation [157]. Three other studies, two using T₄ [158,159] and one using T₃ [160], failed to show any significant effects of thyroid hormone treatment. Finally, an extensive meta-analysis and review of the literature concluded that thyroid hormone treatment failed to reduce neonatal mortality, improve neurodevelopmental outcome, or reduce the severity of the respiratory distress syndrome [161]. Thus, there is no indication currently for the use of thyroid hormone treatment for premature infants.

Thyroid Hormone Therapy in Cardiac Surgery

Within 15 to 30 minutes after placing the patient on bypass, serum T₄ and T₃ levels fall and serum rT₃ levels increase [162]. These alterations may persist for several days postoperatively [102,120]. These changes also have been observed in off-pump cardiopulmonary bypass [122]. Alterations of thyroid hormone parameters during and after cardiopulmonary bypass have been confirmed by multiple human and animal studies [102,120,121,163-166]. The etiology of these rapid changes in thyroid hormone concentrations remains unclear; one proposal suggests that these alterations may result from enhanced degradation of TBG [41]. Experimental studies of animals have shown that T₃ replacement after cardiopulmonary bypass significantly improves cardiac contractility and left ventricular function and decreases systemic vascular resistance [167-170]. Initial studies on the use of T₃ for humans undergoing cardiac surgery suggested that hormone-treated patients may require less ionotropic support [171] and have improved hemodynamic parameters [172]. However, the clearly demonstrable benefit of T₃ repletion in animals has not been translated into similar benefits for humans undergoing coronary artery bypass in controlled clinical trials. A large placebo-controlled trial [173] found no effect of T₃ on any postoperative hemodynamic parameters, although a follow-up report of this same patient group suggested a lower incidence in atrial fibrillation for the T₃-treated group after the first postoperative day [174]. However, a lack of effect for T₃ was shown conclusively in a double-blind, placebo-controlled trial [175], as there were no significant differences in the incidence of arrhythmia or the need for ionotropic support or vasodilator drugs in the 24 hours following surgery or in perioperative mortality or morbidity between the T₃ and the placebo groups. Somewhat more promising results have been reported for children undergoing cardiac surgery with improved hemodynamic parameters and a suggestion that
the need for intensive postoperative care is decreased with intravenous L-T₃ [176,177]. Further studies may be indicated in this population. However, despite the promise of animal studies, there is no indication for the routine use of T₃ in adult patients undergoing cardiac surgery.

**T₃ for Brain-Dead Potential Heart Donors**

After brain death occurs, there is a progressive reduction in cardiac contractility, depletion of high-energy phosphates, and accumulation of tissue lactate [178,179]. These changes coincide with a rapid decline in serum T₃ concentrations and an increase in serum rT₃ concentrations within minutes to hours. An initial study of human heart donors [179] showed that T₃ treatment in human heart donors results in hemodynamic stability, a decrease in ionotrophic support, and preservation of cardiac function prior to transplantation. At least four other groups have subsequent beneficial effects of T₃ therapy in conjunction with other hormones for organ donors, especially those that are unstable [180]. Two other groups found no significant clinical effects of T₃ over placebo on human donor cardiac function [178,181], provided there was no antecedent cardiac dysfunction of the donor. Another study examined the use of T₃ to resuscitate impaired donor hearts with lower ejection fractions, higher filling pressures, and increased ionotrophic support prior to transplantation [178,182]. Subsequently, several consensus conferences held in the United States and Canada have recommended the use of hormonal resuscitation consisting of T₃ (4 μg bolus followed by a 3 μg per hour infusion), vasopressin, methylprednisolone, and insulin for donors whose cardiac ejection fraction is less than 45% in an effort to increase the suitability of hearts for transplantation [180,183]. Thus, T₃ may be beneficial to stabilize or improve cardiac function of donors prior to cardiac transplantation.

**Thyroid Hormone Therapy in Congestive Heart Failure**

When T₃ and thyroid hormone analogs were initially studied as adjuncts to the treatment of heart failure [184,185], the rationale for the use of these hormones had been as pharmacologic agents for their potential ionotrophic properties and interactions with the adrenergic system rather than as hormonal replacement therapy to correct abnormal serum thyroid hormone concentrations. Recently, more attention has been paid to the interactions between the heart and the thyroid hormones for cardiac disease states. For both cardiac failure and hypothyroidism,
cardiac output and cardiac contractility is decreased. Decreased serum T₃ concentrations typical of the sick euthyroid syndrome are often observed among patients with congestive heart failure, whereas serum T₄ concentrations remain normal [186–188]. Importantly, the T₃ found in cardiac myocytes appears to come from the circulating T₃ pool rather than from local deiodination of T₄, indicating that the heart may be more responsive to changes in circulating serum T₃ concentrations [114,115]. Consistent with this observation, similar decreases in cardiac genes, including α-myosin heavy chain, SR calcium ATPase, and β₁ adrenergic receptors, have been observed for both hypothyroidism and in heart failure [114,115]. Finally, low T₃ levels have been determined to be a strong predictor of mortality for patients with congestive heart failure [125,126]. These observations have led several investigators to examine the role of thyroid hormone treatment for patients with congestive heart failure.

An initial uncontrolled study examined the effect of oral T₄ therapy on 20 patients with dilated cardiomyopathy [189]. Cardiac output and functional capacity was increased and systemic vascular resistance decreased. Hamilton et al. [190] examined the effect of a supraphysiologic intravenous infusion of T₃ on cardiac function for patients with New York Heart Association (NYHA) Class III or IV heart failure. Cardiac output increased and systemic vascular resistance decreased without any untoward effects. More recently, Pingitore et al. [191] randomized 20 patients with NYHA Class III or less heart failure to a 3-day intravenous infusion of T₃ or placebo. During the first day of the T₃ infusion, serum T₃ levels were supraphysiologic and then declined to the high normal range on day 2 and 3. The T₃ infusion produced a significant improvement in the neurohumoral profile, with a decrease in serum noradrenaline, N-terminal pro-B-type natriuretic peptide, and aldosterone concentrations, and an increase in left ventricular end diastolic volume. As above normal serum T₃ concentrations were achieved during all or part of these two studies, there is a question of whether the beneficial effects of T₃ are a pharmacologic effect rather than a physiologic one. There are currently no studies on the long-term use of T₃ for the treatment of congestive heart failure. However, as with children undergoing cardiac surgery, more studies may be indicated in this patient population.
Thyroid Hormone Therapy for the Hypothyroid Patient in the Intensive Care Unit

This chapter has discussed the evaluation and management of patients without intrinsic thyroid dysfunction who present with abnormal thyroid hormone parameters as a result of nonthyroidal illness. However, thyroid hormone therapy is needed when the hypothyroid patient presents to the ICU. By definition, the nonthyroidal illness syndrome excludes patients with intrinsic thyroid dysfunction; however, all of the changes in TSH secretion, thyroid hormone metabolism, and thyroid-binding proteins discussed earlier also occur in the hypothyroid patient. As such, the same caveats toward measuring thyroid hormone parameters exist. Most importantly, an admission to the ICU is not the time to determine the adequacy of thyroid hormone replacement in a hypothyroid patient on a previously stable outpatient regimen.

Hypothyroid patients should be continued on their outpatient L-T$_4$ dose. Oral L-T$_4$ is the preferred method for replacing thyroid hormone in a hypothyroid patient. Because of the long half-life of about 7 days of L-T$_4$, the L-T$_4$ dose can be held for 1 to 2 days if the oral route is unavailable. If oral therapy cannot be resumed within 3 days, intravenous L-T$_4$ should be administered. Because less than 75% of an oral dose of L-T$_4$ is absorbed, the intravenous L-T$_4$ dose should be ~75% less than the oral dose. Neither oral nor intravenous L-T$_3$ is indicated in the hypothyroid patient in the absence of myxedema coma.

If hypothyroidism is diagnosed in the ICU setting and initiation of thyroid hormone replacement is required, special consideration should be given to patients with coronary artery disease. In patients with significant preexisting coronary artery disease, starting thyroid hormone may aggravate angina. It is recommended that the initial dose of L-T$_4$ should not exceed 25 $\mu$g for those with known ischemic heart disease and 50 $\mu$g for patients aged 65 years or older without such a preexisting diagnosis.

The oral dose of L-T$_4$ may differ in the ICU setting due to pharmacologic agents or gastrointestinal conditions that may decrease the absorption of L-T$_4$. Patients with jejunooileal bypass surgery, bowel resection, malabsorptive disorders (like celiac disease), and conditions that impair gastric acidity may need adjustment in the dose of L-T$_4$. L-T$_4$ should not be administered within 2 to 3 hours of calcium carbonate, bile acid sequestrants, ferrous sulfate, phosphate binders, sucralfate, and
aluminum-containing antacids as they may interfere with the absorption of L-T$_4$. Also by their effect of decreasing gastric acidity, proton pump inhibitors, if given for a long period, may decrease the absorption of L-T$_4$. 
SUMMARY

In summary, the spectrum of alterations of thyroid hormone concentrations and regulation seen among critically ill patients is the result of a coordinated systemic reaction to illness. The question of whether the sick euthyroid syndrome of critically ill patients represents pathologic alterations of thyroid function that negatively impacts these patients or simply reflects multisystem failure (i.e., respiratory, cardiac, renal, hepatic failure) that occurs among critically ill patients is still debatable [86,192–194]. The interpretation of thyroid function tests of the ICU patient and the identification of patients with intrinsic thyroid dysfunction is often difficult and must take into consideration both the clinical assessment of the patient and the duration and severity of the illness. Whenever possible, it is best to defer the evaluation of thyroid function until the patient has recovered from the critical illness. Thyroid hormone replacement therapy has not been shown to be of benefit in the vast majority of these patients in the published studies to date (Table 143.4 [86]). At the present time, in the absence of any clinical evidence of hypothyroidism, there does not appear to be any compelling evidence for the use of thyroid hormone therapy for any patient with decreased thyroid hormone parameters due to the sick euthyroid syndrome.

NEUROLOGIC PROBLEMS IN THE INTENSIVE CARE UNIT
DAVID A. DRACHMAN • DAVID PAYDARFAR
An Approach to Neurologic Problems in the Intensive Care Unit
DAVID A. DRACHMAN

Neurologic problems present in the intensive care unit (ICU) in two modes: (a) primary neurologic problems, usually under the care of a neurologist or neurosurgeon, and (b) secondary neurologic complications, occurring in patients with other medical or surgical disorders. Only a handful of common clinical situations bring neurologists and patients together in the ICU, although they may be caused by myriad disease states [1]. These situations include:

1. Depressed state of consciousness; coma
2. Altered mental function
3. Required support of respirations or other vital functions
4. Monitoring of increased intracranial pressure (ICP), respirations, state of consciousness
5. Determination of brain death
6. Prevention of further damage to the central nervous system
7. Management of seizures or status epilepticus
8. Evaluation of a neurologic disease that occurs in the course of a severe medical disease
9. Management of a severe medical disease that develops in the course of a neurologic illness

Patients with primary neurologic problems most commonly have conditions with an identified cause, such as stroke, seizures, infectious or
immune meningoencephalitis, Guillain–Barré syndrome, head trauma, or myasthenia gravis. Such patients are admitted to the ICU for close observation and management of vital functions, such as respiration, control of ICP, or arrest of seizure activity. These patients represent the minority of neurologic problems seen in the ICU. Far more frequently the neurologist is called on to evaluate the neurologic complications of medical disease: impairment of consciousness in a patient who has undergone cardiopulmonary resuscitation, development of delirium in an elderly individual with a serious infection, or occurrence of focal neurologic deficits in a patient with a ponderous medical record that reveals long-standing diabetes, renal failure, hypertension, and pulmonary disease.

The questions posed to the neurologic consultant are often imperfectly framed. Background observations regarding the origin, onset, and course of the neurologic abnormality may be unavoidably sparse and the history unavailable. The classic neurologic methodology, which involves a comprehensive history and meticulous examination, is rarely possible in patients encumbered with endotracheal tubes, cardiac monitors, and indwelling arterial and venous lines. For these reasons, neurologists must adopt special strategies to function effectively in the ICU, focusing sharply on the specific question with which they are dealing.

INDICATIONS FOR NEUROLOGIC CONSULTATION IN THE INTENSIVE CARE UNIT

Depressed State of Consciousness

The patient with the most common of ICU neurologic problems—a depressed state of consciousness, ranging from lethargy to coma—raises a host of questions. Does the patient have a focal brainstem lesion or diffuse cerebral involvement? Is there an anatomic lesion or a metabolic disorder? Have vital brainstem functions been impaired? Is ICP increased?

The most common primary neurologic causes of depressed consciousness include head trauma, intracranial hemorrhage, post cardiac arrest anoxia–ischemia, and less commonly, inapparent seizures. The secondary conditions seen most often are metabolic, such as anoxia, drug intoxication, or diabetic ketoacidosis. Sometimes the diagnosis is evident, as in head trauma; at other times, determination of the cause of depressed consciousness may present a diagnostic challenge, demanding
a race against the clock to avoid irreversible changes. In every case, it is crucial to establish whether depressed consciousness is due to intrinsic brainstem damage, increased ICP, toxins, widespread anoxia or ischemia, or some other less common cause. It is particularly important to sort out rapidly the component(s) that may be treatable.

Examination of the patient with depressed consciousness exemplifies some of the difficulties of neurologic care in the ICU. Details of this examination are described elsewhere [2]. Like the standard neurologic examination, however, it includes evaluation of mental status, cranial nerve functions, motor functions and coordination, reflexes, sensation, and vascular integrity. The observations made must be used to answer the questions posed above, supplemented by appropriate laboratory studies when possible.

A detailed evaluation of memory and cognitive function is rarely possible for patients who are lethargic, and never possible in those who are stuporous or comatose. Instead, the physician must estimate the patient’s responsiveness. Can the patient say any words or respond to commands? Does the patient open his or her eyes? Does the patient groan in response to a painful stimulus or attempt to remove it in a purposeful way? What is the status of the vital functions? Is the respiratory pattern disturbed? The Glasgow Coma Scale score is a simple, but useful, way to document the patient’s sensorium [3].

Cranial nerve evaluations include determination of vision, done by observing how the patient follows a large object or a light, gazes toward right and left visual fields, or blinks to a visual threat. Pupillary size, equality, and responsiveness to light are assessed. Corneal reflexes, cough, and vibrissal (nasal) reflexes are evaluated. “Doll’s eyes” (vestibuloocular) responses are determined by rotation of the head from side to side; if they are absent, ice water caloric testing can be carried out. Facial movements are assessed in response to painful supraorbital stimuli; the gag reflex is tested in the usual fashion.

Motor function is evaluated as completely as possible. All limbs are observed for spontaneous movement and symmetry as well as tremor or other adventitious movements. If no spontaneous movements take place, a pinch or other noxious stimulus can be used to observe purposeful defensive movements. Decerebrate (i.e., four-limb extensor) and decorticate (i.e., upper limbs flexor, lower limbs extensor) rigidity are observed. Tone is assessed passively for spasticity or rigidity. Deep tendon reflexes are checked in the usual way, working around restraints and intravenous tubing. Grasp, suck, snout, and plantar reflexes are
Pain is often the only sensory modality that can be tested. The physician must determine whether withdrawal from pinch or pinprick is appropriately defensive or (in the lower extremities) merely part of an exaggerated extensor–plantar response with triple flexion (flexion at hip, knee, and great toe), which may be mistaken for purposeful withdrawal. Finally, the vascular status is evaluated by listening for bruits over the carotid and subclavian arteries, the vertebral arteries, and the orbits.

Such an examination reveals the patient’s state of consciousness, the integrity of brainstem reflexes, and the presence or absence of lateralizing or focal neurologic deficits. The value of the systematic (if limited) neurologic examination cannot be overestimated. For example, in a comatose patient, the finding of decerebrate rigidity that points to significant damage at the level of the pons may be more valuable than many laboratory studies, and unilateral weakness of limbs with ipsilateral hyperreflexia indicates a focal brain disorder rather than a diffuse metabolic problem.

Neurodiagnostic studies are often critical in the analysis of comatose patients in the ICU, but the patient’s immobility and dependence on life support systems present special difficulties. A neuroradiology suite that is distant from the ICU presents additional obstacles. It is frequently difficult to obtain an MRI (magnetic resonance imaging) or CT (computed tomographic) brain scan, or arteriogram on a patient who is dependent on a respirator. Paradoxically, in patients with the most urgent problems, it is often least convenient to obtain the maximum amount of neurodiagnostic information. The decision that a patient is too sick to have the crucial study performed is often incorrect. In such desperate cases, risks must be taken to obtain lifesaving information.

Management of the patient with depressed consciousness depends largely on the cause. Techniques for eliminating toxins, reducing ICP, and maintaining vital functions must be applied, depending on the diagnostic context (see Chapter 145).

**Altered Mental Function**

In patients who remain relatively alert, other organic disorders may affect mental function, producing an often perplexing variety of clinical patterns. These include confusion, delirium, aphasia, and isolated memory impairment. The first question for the physician is whether the patient’s abnormal mental function represents a recent change that is part of the present illness, or instead is part of a long-standing problem. It is also critical to note whether the change developed abruptly (e.g., after surgery or cardiac arrest) or if there is no known precipitating event; and whether it is improving, worsening, or stable.
Confusion and delirium are commonly reversible and generally result from metabolic and toxic disorders (see Chapters 145 and 157). Persistent aphasia and isolated memory impairment suggest focal damage to the brain, and an anatomic lesion should be sought. Dementia—cognitive and memory impairment—cannot be accurately evaluated in patients who have a depressed state of consciousness or the other mental changes indicated above. When dementia occurs de novo in a patient with a clear sensorium, it may indicate either reversible conditions (e.g., drug-induced, depression-related) or irreversible damage (e.g., diffuse anoxia or ischemia; see Chapter 145).

Any recent change in mental status in a patient in the ICU requires prompt investigation. Whether it signals worsening of the underlying medical disorder or direct involvement of the brain, the change should be assessed by an experienced neurologist as early in its evolution as possible, before it is complicated by the passage of time, advance of disease, and effects of additional treatments.

Support of Respiration and Other Vital Functions

Respiratory support is needed for neurologic patients in two circumstances: loss of brainstem reflex control of respiration and impairment of effective transmission of reflex impulses to functioning respiratory muscles. Ischemia, anoxia, compression, hemorrhage, and toxic depression may alter brainstem control of respirations, producing characteristic respiratory patterns that depend on the site of damage [2], such as central neurogenic hyperventilation, Cheyne–Stokes or periodic breathing, or apnea. The intensivist and neurologist should be familiar with the use of positive end-expiratory pressure and other ventilatory regimens, operation and interpreting readout of the hospital’s respirators, and the endotracheal intubation equipment. Further, the neurologist must understand the neurologic significance of different respiratory patterns, which are as much a part of the ICU neurologic examination as is reflex testing.

Effective transmission of respiratory impulses may be impaired at the cervical spinal cord, anterior horn cells, peripheral nerves, neuromuscular junctions, or muscles of respiration. Cervical traumatic injuries, amyotrophic lateral sclerosis, Guillain–Barré syndrome, myasthenia gravis, and muscular dystrophy may interfere with breathing at the respective levels noted. Some of these conditions are transitory (e.g., Guillain–Barré syndrome) or treatable (e.g., myasthenia gravis), with complete recovery depending largely on the success of maintaining respiration. Even in incurable conditions (e.g., amyotrophic lateral sclerosis), sustaining respiration during periods of decompensation, such as respiratory infections, can prolong life significantly.
Monitoring of Intracranial Pressure and State of Consciousness

In a number of neurologic disorders, extremely close observation is needed to avoid the development of dangerous, often irreversible, further damage to the brain. The most common disorder requiring such monitoring is head trauma. The lethargic patient must be carefully observed for evidence of increasing ICP due to cerebral edema, intracranial (subdural, epidural, intracerebral) hemorrhage, or both [4].

The need for prompt recognition and early treatment of significantly increased ICP cannot be overemphasized. Once uncal or tonsillar herniation with brainstem compression and development of Duret hemorrhages has occurred, the consequences of this secondary effect of brain injury may far outweigh the initial damage. (The methods for monitoring ICP with pressure-detecting catheters or bolts and assessing consciousness and brainstem functions with the Glasgow Coma Scale are described in Chapters 31 and 41.)

Determination of Brain Death

With the recognition that death of the brain and brainstem is equivalent to death of the patient, even though the heart continues to beat and respirations are sustained by artificial ventilation, the need to ascertain brain death has become more critical [5]. Early identification of brain death has three important justifications: (a) the use of viable donor organs for transplantation; (b) the termination of the hopeless vigil of a distraught family; and (c) the freeing of ICU beds for patients who may be helped. When one or more of these conditions prevails, it is important to determine the occurrence of brain death promptly. When none of the conditions is present, there is no urgency in declaring the patient brain dead.

It should be emphasized that brain death is specifically a determination that the brain and the brainstem are already dead—not a prediction that useful recovery is unlikely. It is also true that the longer one waits in even marginally uncertain cases, the clearer the evidence of brain death becomes. (The criteria for brain death are discussed extensively in Chapters 56 and 145.) The “CADRE” mnemonic may be useful in recalling the established criteria for brain death, in the absence of sedative drugs: Coma; Apnea; Dilated, fixed pupils; Reflex (brainstem) absence; and Electroencephalographic silence.
Prevention of Further Damage to the Central Nervous System

A variety of neurologic disorders have the potential to cause further damage to the central nervous system. Acute strokes, or stroke in evolution, for example, may be arrested by thrombolytic treatment [6], endovascular clot removal [7] or angioplasty, and stenting. These modalities may limit or even reverse the underlying ischemic process; and neuroprotective agents may, in the foreseeable future, prevent further damage. Coma following cardiac arrest should be promptly treated with hypothermia to preserve neurologic function [8]. Spinal cord compression by metastatic tumor urgently requires surgical decompression followed by radiation therapy to avoid irreversible complete cord transection [9]. Among the infectious diseases of the nervous system, bacterial meningitis and certain treatable encephalitides (e.g., herpes simplex) require the immediate institution of antibiotic or antiviral therapy; spinal epidural abscess requires prompt surgical decompression as well. Although much of neurologic practice involves disorders for which progress is measured in months or years, cerebral anoxia, ischemia, hemorrhage, increased ICP, spinal cord compression, infectious diseases, and other acute disorders require prompt institution of treatment to avoid extension of the initial process. It is useful to remember that, as a largely postmitotic structure, the brain has a limited capability for regeneration, and its ability to survive without a continuing supply of nutrients is measured in minutes. Only in the ICU, with its facilities for careful monitoring and adjustment of therapy, can many of these treatments be successfully carried out.

Management of Status Epilepticus

Unlike simple, brief seizures, status epilepticus threatens lasting deficits or death if not controlled (see Chapter 151). Any patient whose sequential seizures cannot be arrested promptly with routine management (e.g., intravenous benzodiazepines, phenytoin) must be observed in the ICU, where therapy ranging up to general anesthesia with artificial ventilation may be required.

Evaluation of Neurologic Disease Accompanying Severe Medical Disease

Neurologic signs or symptoms develop in many patients admitted to the ICU for myocardial infarction, subacute bacterial endocarditis, cardiac arrhythmia, pneumonia, acute respiratory distress syndrome, septic shock, renal disease, hepatic failure, and other similar disorders while
they are under treatment for the primary medical problem. Numerous questions are raised: Is the neurologic finding a consequence of the underlying disease, or is it coincidental? Does it demand further investigation at once, or can it wait? Should therapy be changed, or should new therapy be started? These issues demand the attention of the neurologist.

Management of Severe Medical Disease Accompanying Neurologic Illness

For patients with severe medical disease accompanying neurologic illness, unrelated medical illness most often develops in the setting of a chronic neurologic disorder. The demented patient may experience a myocardial infarction, or septicemia may develop in the patient with multiple sclerosis. Indirect relationships should be sought. Does the demented patient have multiple cerebral emboli from underlying cardiac disease? Is the patient with multiple sclerosis septicemic from a bladder infection due to impaired urinary control? Early recognition of a change in the seriousness of the neurologic patient’s condition is often difficult, but it may be critical to a successful outcome.
PROGNOSTIC AND ETHICAL CONSIDERATIONS

When severe damage involves the brain, either as a separate neurologic condition or as a secondary consequence of other medical disease, the physician who requested neurologic consultation and the family often need guidance regarding the probable outcome. There are three critical questions: Will the patient survive? Has irreversible brain damage occurred? What is the likely degree of residual disability?

There are few simple rules that can be applied infallibly to determine the prognosis in, for example, comatose patients, especially early in the course. The most important consideration is often whether irreversible damage has affected crucial areas of the brain, rather than the depth of impairment of consciousness. The patient with glutethimide poisoning, for example, may show no evidence of any neurologic function yet can recover fully if vital functions are maintained. In contrast, the comatose patient with head trauma resulting in pontine hemorrhage and decerebrate rigidity may have a far worse prognosis. The probability of neurologic recovery generally declines with advancing age, size and location of the lesion, and duration of deficit. A number of studies have provided statistical guidelines that are of value in gauging the probability of recovery [10,11]. Guidelines for the evaluation of prognosis following cardiac arrest and resuscitation are particularly well documented, and the absence of pupillary and corneal reflexes or motor response to pain, the occurrence of myoclonic status epilepticus, absence of somatosensory evoked potentials (N20), and elevated neuron-specific enolase are particularly useful in early determination of poor prognosis [10].

Early in the course of coma, the physician should not be hasty in abandoning hope and vigorous medical efforts to maintain survival and to limit neurologic damage. Late in the course, or as poor prognostic signs accumulate, it is important to recognize the outer limits of possible recovery and to assess the value of continuing life support accordingly. The patient’s wishes, expressed in a living will or durable power of attorney for health care and as interpreted by close, responsible family members (“substituted judgment”), should combine with the physician’s prognostic judgment to help determine a medical course of action. Although management in the ICU usually entails the unstinting use of every available means of life support and treatment, there must eventually be a transition either to recovery or to a permanent state of dependence, and the nature and extent of continued treatment should be adjusted accordingly. The technical means of maintaining survival almost
indefinitely by the use of extraordinary measures is now available. It is important for the physician and the patient’s family to consider whether, in the case of a patient with irreversible and severe neurologic damage, they are extending life or prolonging the process of dying [12].

It is clear that neurologic problems abound in the ICU. A successful approach to these disorders requires the physician to recognize the nature of the clinical situation prompting neurologic consultation or admission to the ICU. An analysis of which of the nine types of neurologic clinical situations is being encountered often guides the physician initially in diagnosis and management. The following chapters discuss some of the more common neurologic problems encountered in the ICU, with specific attention to management in the ICU and a broader view of the neurologic conditions in general.

Evaluating the Patient with Altered Consciousness in the Intensive Care Unit

RAPHAEL A. CARANDANG • LAWRENCE J. HAYWARD • DAVID A. DRACHMAN

The spectrum of disease that leads to acute impairment of consciousness is broad; the disorders are varied and potentially life-threatening and may be treatable if recognized early. The clinician evaluating the patient with an altered level of consciousness must do so in a systematic and efficient fashion. The approach consists of (a) rapidly determining the type of mental status change, (b) administering life-support measures where urgently needed, (c) obtaining a detailed history and physical examination directed at determining more precisely the cause(s) of the nervous system disorder, (d) selecting appropriate and informative diagnostic and laboratory studies, and (e) initiating more definitive treatment based on this assessment.

As a practical matter, consciousness refers to a state of awareness of self and environment that depends on intact arousal and content [1,2]. Arousal is the level of attentive wakefulness and readiness to respond to relevant sensory information. Alerting stimuli activate the ascending reticular activating system (ARAS), which extends from the superior pons to the thalamus and projects to multiple cortical areas. Diminished arousal implies dysfunction of either the ARAS or both cerebral hemispheres; lesions of the brainstem sparing the ARAS (e.g., of the medulla) or of only one hemisphere do not affect wakefulness. This chapter defines altered states of consciousness and presents a systematic approach to bedside evaluation and prognostication of the comatose patient.
ALTERED STATES OF CONSCIOUSNESS

Neurologists are frequently consulted for evaluation of patients who appear unconscious, confused, or awake and alert but noncommunicative.

Patient Who Appears Unconscious

Patients who appear unconscious lie mostly motionless, usually with the eyes closed and seemingly unaware of their environment. The causes of this condition include normal sleep, depressed consciousness, psychogenic coma, locked-in state, vegetative states, minimally conscious state, and brain death.

Sleep

The normal unconsciousness of sleep is characterized by prompt reversibility on threshold sensory stimulation, and maintenance of wakefulness following arousal. The degree of stimulation required depends on the stage of sleep (stage IV non–rapid eye movement sleep is the deepest), and the sensory stimulation used.

Depressed Consciousness

Consciousness is deemed depressed when suprathreshold sensory stimulation is required for arousal and wakefulness cannot be maintained unless the stimulation is continuous [1,2]. Responsible specific lesions involve the ARAS, or both cerebral hemispheres. Brainstem damage may be direct, or due to indirect compression by masses situated in other compartments. Bilateral cerebral hemispheric damage may be due to multifocal insults, or to large unilateral lesions with resulting major mass effect. In addition, a wide array of metabolic derangements, toxins, or diffuse injuries may depress consciousness by affecting the ARAS, the cerebral hemispheres, or both. The spectrum of depressed states—lethargy, hypersomnolence, obtundation, stupor, and coma—is defined by the level of consciousness observed on examination. The etiologies are diverse (Table 145.1), with the degree of depression dependent on the nature of the insult, its duration, and the location and extent of involvement of the brain.

| TABLE 145.1 Differential Diagnosis of Depressed Consciousness |
The first signs of brain dysfunction may be mild and barely noticeable. The patient may be described initially as confused or drowsy before progressing to *lethargy* or *hypersonomolence* and eventually to a more depressed state. Hypersonmolent patients maintain arousal only with vigorous and continuous sensory stimulation; while awake, however, they may be oriented and make appropriate responses. The most common cause of hypersonolence in the hospital is sleep deprivation, mostly iatrogenic, especially in the around-the-clock care setting of the intensive care unit (ICU). Patients with discrete diencephalic or midbrain tegmentum lesions may also present with hypersonolence [3,4]. Because these lesions affect the ARAS and spare the cerebral hemispheres, cognitive content is usually preserved. Rostral extension of a midline lesion may involve thalamic structures (especially the dorsomedial nuclei) and cause difficulties with the ability to store new memories. Other mesencephalic structures may be affected and cause abnormalities of pupillary function, internuclear ophthalmoplegia, and third nerve dysfunction.

*Obtunded* patients usually can be aroused by light stimuli but are mentally dulled and unable to maintain wakefulness. *Stuporous* patients can be aroused only with vigorous noxious stimulation. While awake,
neither obtunded nor stuporous patients demonstrate a normal content of consciousness, but both may display purposeful movements, attempting to ward off painful stimuli or to remove catheters, endotracheal tubes, or intravenous lines.

Patients in coma are unresponsive to suprathreshold sensory stimulation, including noxious stimulation that is strong enough to arouse a deeply sleeping patient but not strong enough to cause physical injury. Although the patient usually lies motionless, movements such as stereotyped, inappropriate postures (decerebration and decortication) and spinal cord reflexes (triple flexion and Babinski responses) may occur. Irrespective of the etiology, the duration of coma is typically no longer than 2 to 4 weeks, after which one of the three conditions supervenes: arousal to full or partial recovery, a vegetative state, or death.

Most of the literature on prognosis of comatose patients comes from nontraumatic coma, largely anoxic–ischemic brain injury. A landmark paper by Levy, Plum, and associates from 1981 established the neurologic examination—particularly absence of brainstem reflexes including pupillary, corneal, and oculocephalic reflexes—as important predictors of poor outcome in nontraumatic coma [5]. Multiple studies followed which confirmed the importance of motor responses in addition to brainstem examination, and some diagnostic tests were established as useful in predicting outcomes; these are well summarized in the American Academy of Neurology Practice Parameter on post-cardiopulmonary resuscitation by Wijdicks et al., published in 2006 [6]. Given the life-or-death responsibility of the physician providing a prognosis, only clinical indicators or diagnostic tests that are highly specific with a near-zero false-positive rate are utilized. A poor outcome is predicted by the absence of pupillary and corneal reflexes, absent or extensor motor responses, absent responses to caloric testing of the oculovestibular reflex at day 3 post-arrest, and the presence of myoclonic status epilepticus on day 1 post-arrest. The absence of N20 responses on somatosensory evoked potential (SSEP) testing, and the finding of serum neuron-specific enolase levels more than 33µg per L on days 1 to 3 post-arrest also indicate a poor prognosis (Fig. 145.1). Prognostication must include consideration of the etiology of the disease process, the clinical examination findings, and radiologic evidence of damage to the upper pons, midbrain, diencephalon, and other vital structures for arousal.
Psychogenic Coma

Patients in psychogenic coma appear comatose but have clinical and laboratory evidence of wakefulness [1]. Psychogenic unresponsiveness may be suggested by active resistance or rapid closure of the eyelids, pupillary constriction to visual threat, fast phase of nystagmus (i.e., a saccade) on oculovestibular or optokinetic testing, and avoidance of self-injury (e.g., by averting an arm dropped toward the patient’s face) or annoying stimulation such as a nasal tickle (moving head away from stimulus). Caloric testing with ice water irrigation of the ear will elicit a normal nystagmoid response with the fast phase directed away from the irrigated ear, and possibly some nausea and vomiting. Deep tendon reflex examination is often normal but can be voluntarily suppressed.
Electroencephalogram (EEG) α waves that attenuate with eye opening are inconsistent with coma or sleep. Most diagnostic tests will be unrevealing. Psychiatric conditions that may be associated with psychogenic coma are conversion reactions secondary to hysterical personality, severe depression, or acute situational reaction, catatonic schizophrenia, dissociative or fugue states, severe psychotic depression, and malingering.

Locked-In State

The locked-in state is a nearly total paralysis without loss of consciousness [7, 8]. Because the most common cause of this state is destruction of the base of the pons, the patient is completely paralyzed except for muscles subserved by midbrain structures (i.e., vertical eye movements and blinking). Consciousness is preserved because the ARAS is located in the tegmentum of the pons, dorsal to the damaged area. The most frequent cause is cerebrovascular such as cerebral infarction from a basilar thromboembolism, or pontine hemorrhage from uncontrolled hypertension; less frequent etiologies of the syndrome are acute polyneuropathy (Guillain–Barré syndrome), acute poliomyelitis, or toxins that block transmission at the neuromuscular junction. It is important to note that locked-in patients are capable of hearing, seeing, and feeling external stimuli and pain. Adequate analgesia and anxiolysis should be provided despite the absence of external signs of pain and anxiety. A 5- to 10-year survival has been reported in as high as 80% of patients in some series and a surprising 58% of patients surveyed reported satisfaction with life despite their disability in a small case series [8].

Brain Death

The term brain death refers to a determination of physical death by brain-based, rather than cardiopulmonary-based, criteria [9]. Brain death is the irreversible destruction of the brain, with the resulting total absence of all cortical and brainstem function, although spinal cord reflexes may remain [10, 11]. It is not to be confused with severe but incomplete brain damage with a poor prognosis or with a vegetative state, conditions in which some function of vital brain centers still remains. In brain death, support of other organs is futile for the patient, whereas when there is some residual brain or brainstem function, or a vegetative state, decisions regarding ongoing life support clearly depend on the
wishes of the patient or his or her proxy.

In brain death, pupils are midposition and round (not oval), and apnea persists even when arterial carbon dioxide tension (PCO$_2$) is raised to levels that should stimulate respiration. Table 145.2 summarizes the guidelines used in the United States. Brain death may be simulated by drug intoxications and cannot be evaluated when toxic drugs are present; depending on preserved renal and hepatic function, most such toxic effects do not persist longer than 36 hours. Hypothermia also precludes a diagnosis of brain death, and the patient must be brought to normal temperature prior to declaring death. Brain death is a clinical diagnosis, but ancillary tests such as an EEG and blood flow studies (transcranial Doppler, technetium-99m scan, or conventional cerebral angiography) may be useful where the clinical examination is compromised by sedating medications. Unresponsiveness that can mimic brain death may occur with extensive brainstem destruction, for example, after basilar artery thrombosis. Despite absent brainstem reflexes, continued cortical activity on the EEG and persistent cerebral blood flow would demonstrate that the patient is not brain dead.

rooting reflexes
Absence of respiratory drive at PaCO$_2$ 60 mm Hg, or 20 mm Hg above normal baseline values
Interval between two separate examinations varies depending on the age of the patient if pediatric, but for adults is usually at least 6 h

3. Ancillary diagnostic tests:
   - EEG showing electrocerebral silence
   - Technetium (99mTc) hexametazime nuclear scan showing absence of activity in brain
   - Cerebral angiography showing absence of blood flow in cerebral vessels
   - Transcranial Doppler showing lack of diastolic or reverberating flow and small systolic peaks in early systole

CNS, central nervous system.

The American Academy of Neurology has published practice parameters for the determination of brain death. The criteria take into account etiology, performance of two separate clinical examinations 6 hours apart, and include the method of apnea testing with preoxygenation and oxygen [11]. As criteria for brain death vary from state to state, and procedures to determine brain death differ among institutions, it is important to be familiar with the guidelines in your institution [12]. The occurrence of brain death provides the opportunity for organ donation, and most institutions have a protocol that includes informing organ bank organizations to facilitate this.

**Patient Who Appears Confused**

*Confusion* is a general term used for patients who do not think with customary speed, clarity, or coherence. The causes of this condition include among others an acute confusional state, toxic encephalopathies, dementia, inapparent seizures, and receptive aphasia.
Acute Confusional State

When the cerebral hemispheres are negatively affected by toxic, metabolic, anoxic, structural, or infectious processes, the patient may appear acutely confused [13,14]. Poor arousal and an abnormal content of consciousness may contribute to the clinical presentation, and the etiologies are legion (Table 145.3). Patients with clouded consciousness are easily distracted or startled by environmental stimuli. Their processing of information is slow and effortful, state of consciousness fluctuates from drowsiness to hyperexcitability, attention span is poor, and recall and recent memory are impaired. If sensorial clouding becomes more advanced, sensory input is increasingly misinterpreted, daytime drowsiness alternates with nocturnal agitation, disorientation for place and time becomes apparent, and repeated prompting is required for a response to even the simplest commands.

**TABLE 145.3 Classification of Acute Confusional States**

| ACS not associated with focal or lateralizing neurologic signs and normal CSF
| Metabolic disorders
| Hepatic encephalopathy
| Uremia
| Hypercapnia
| Hypoglycemia
| Diabetic ketotic coma
| Porphyria
| Hypercalcemia
| Infectious disorders
| Septicemia
| Pneumonia
| Typhoid fever
| Rheumatic fever
| Drug intoxication
| Opiates
| Barbiturates
| Tricyclic antidepressants
| Other sedatives
| Amphetamines
| Anticholinergic medications
| Abstinence states (i.e., withdrawal states)
| Alcohol (delirium tremens)
Barbiturates
Benzodiazepines
States that reduce cerebral blood flow or oxygen content
Hypoxic encephalopathy
Congestive heart failure
Cardiac arrhythmias
Situational psychoses (diagnoses)
Postoperative psychosis
Posttraumatic psychosis
Puerperal psychosis
Intensive care unit psychosis
ACS associated with focal or lateralizing neurologic signs and/or abnormal CSF
Cerebrovascular disease or space-occupying lesions (especially of the right parietal, inferofrontal, and temporal lobes)
Ischemic infarct
Neoplasm
Abscess
Hemorrhage (intraparenchymal, subdural, epidural)
Granuloma
Infectious disorders
Meningitis
Encephalitis
Subarachnoid hemorrhage
Cerebral contusion and laceration
ACS sometimes associated with focal or lateralizing neurologic signs
Postconvulsive delirium
Acute hydrocephalus
Nonconvulsive status epilepticus
Nonketotic diabetic coma

These disorders may be associated with signs of psychomotor overactivity or delirium.
ACS, acute confusional state; CSF, cerebrospinal fluid.

Delirious patients typically manifest acutely fluctuating confusion, with
psychomotor overactivity, agitation, autonomic instability, and often visual hallucinations. Clinical observations frequently suggest that the disturbance of cognition or perception is directly related to a potentially reversible general medical condition rather than to an evolving dementia. Hyperexcitability may alternate with periods of drowsiness or relative lucidity. Signs of autonomic overactivity include pupillary dilatation, diaphoresis, tachycardia, and hypertension. Patients with delirium may not sleep, sometimes for periods of several days; the success of treatment can be judged by the development of normal sleep. Delirium tremens, the most serious consequence of ethanol withdrawal, is perhaps the best-known example of this state. Because the routine Mini-Mental State Examination often cannot be administered to unstable, intubated patients, alternative screening tools have been developed for early detection and monitoring of delirium in the ICU [15,16]. Validated tools such as the Confusion Assessment Method, or CAM-ICU scale, have the advantage of being simple and easy to administer, highly reliable and applicable in patients who are intubated. Systematic screening may help detect early delirium and allow prompt, cost-effective treatment. Delirium has been linked to prolonged ICU stay and ventilator days, and is associated with postdischarge cognitive dysfunction and worse 6-month mortality outcomes [16,17]. The use of interventions that reduce delirium in the ICU include reduction and intermittent use of sedatives, or spontaneous awakening trials, as well as sedation with α adrenergic medications such as dexmedetomidine [18,19].

In beclouded dementia, confusion is superimposed on an underlying subacute or chronic cognitive disorder. The preexisting cerebral dysfunction may be mental retardation, dementia, or the deficits from a vascular, neoplastic, or demyelinating process. In some cases, the underlying disorder is not diagnosed until the confusion appears during an intercurrent illness (e.g., sepsis or infection, congestive heart failure, surgical procedures, anemia, drug overdose, or intolerance).

### Dementia

Patients with dementia have subacute or chronic intellectual dysfunction unaccompanied by a reduction in arousal [20]. The patient exhibits a decline in multiple cognitive functions, including memory, language, spatial orientation, personality, abstract thinking, and insight. The ability to carry out testing requires relative preservation of attention and language comprehension. The causes of dementia include degenerative processes (Alzheimer’s disease, frontotemporal degeneration, Lewy body dementia, Huntington’s disease), metabolic and nutritional disorders (Wernicke–Korsakoff’s syndrome with thiamine deficiency, hypothyroidism, pellagra, vitamin B₁₂ deficiency), infectious diseases
Inapparent Seizures

Patients with nonconvulsive status epilepticus may appear disoriented, episodically unresponsive, or alternately lucid and confused; the EEG shows continuous or frequent epileptiform discharges \[21,22\]. Careful observation may alert the clinician to seizure phenomena, such as episodic staring, eye deviation or nystagmoid jerks, facial or hand clonic activity, and automatisms. The syndrome may be the result of a generalized (absence) status or a complex partial status. Complex partial status is the more common form seen in the ICU and may not be preceded by a history of complex partial seizures. The origin of the abnormal focal discharge may be from the temporal, frontal, or occipital lobes, and the EEG pattern during the ictus is variable. Inapparent seizures may occur in as many as 19% of all patients in the ICU, and 56% of patients who are comatose at the time of monitoring. The yield of EEG monitoring is increased by continuous monitoring for 24 hours \[23\]. Nonconvulsive status epilepticus should be considered, and is the cause of otherwise unexplained coma in as many as 8% of patients \[24\]. A benzodiazepine, such as diazepam or lorazepam, or an anticonvulsant drug may eliminate the discharge and improve the patient’s state of consciousness.

Receptive Aphasia

Patients with receptive aphasia often appear confused because they have a disorder of language comprehension \[14\]. The patient is awake and alert but unable to comprehend written or verbal commands despite voluminous (fluent) spontaneous speech. Paraphasias may be present (especially when the patient is asked to name objects) and consist of either inappropriately substituted words or nonsensical jargon. The responsible lesions are located in the dominant temporoparietal cortex and are often associated with subtle focal neurologic signs, including mild pronator drift of the right hand, right homonymous hemianopsia or superior quadrantanopsia, and right-sided sensory loss; gross
hemiparesis is usually not found, as the frontal motor cortex is not affected.

**Patient Who Appears Awake and Alert but Noncommunicative**

Although sensory stimulation may arouse these patients, they seem unable or unwilling to speak. The causes of this condition include mutism, akinetic mutism, and the persistent vegetative state.

**Mutism**

Mutism is a manifestation of many clinical conditions, including aphonia, anarthria, oral-lingual apraxia, and aphasia. Only in aphasia, however, is written expression also impaired (i.e., agraphia).

Aphonia due to paralysis of the vocal cords and anarthria due to paralysis of the articulatory muscles are usually evident clinically in patients who are unable to make sounds but who mouth words appropriately. Oral-lingual (facial) apraxia is a disorder of learned mouth movements (e.g., speaking, blowing kisses, sucking through a straw, protruding the tongue to command) seen with isolated and discrete lesions involving the facial area of the dominant motor cortex. Patients with expressive aphasia are unable to communicate normally by verbal or written language. Nonfluent (Broca’s) aphasia with diminished “telegraphic” output is usually intensely frustrating to the patient; occasionally, singing his or her words, rather than merely saying them, improves speech. Lesion location differs depending on whether comprehension is also affected or whether comprehension and repetition of words are relatively preserved or lost. At the least, the dominant frontal cortex is involved, and some degree of right hemiparesis is usually present.

**Abulia**

Patients with abulia “lack will” and are apathetic with slow to no responses to verbal stimuli and do not initiate any activity or conversations. When adequately stimulated, these patients appear to be cognitively intact. In contrast to the obtunded or stuporous patient, they are fully, alertly awake. Abulic patients often have bilateral frontal
lobe disease. Specific regions implicated include the anterior cingulate cortex but also been described in other subcortical lesions.

**Akinetic Mutism**

Patients with akinetic mutism appear alert and exhibit sleep–wake cycles, but they show little evidence of cognitive function and do not meaningfully interact with the environment [1,14]. Brainstem function is intact, and patients may open their eyes to verbal stimuli or track moving objects. They have a paucity of movement even to noxious stimulation, despite little evidence of corticospinal or corticobulbar damage. Akinetic mutism is a more severe form of abulia and is associated with large bilateral lesions of the basomedial frontal lobes, small lesions of the paramedian reticular formation in the posterior diencephalon and midbrain, and subacute communicating hydrocephalus.

**Persistent Vegetative State**

Patients in a persistent vegetative state are also akinetic and mute but lack outward manifestations of any significant brain activity other than reflex responses [1,14]. These may include decerebrate or decorticate posturing, deep tendon reflexes, Babinski or triple flexion reflexes, yawning, and so on. The term is usually reserved for the patient who has recovered only to this extent from coma due to a severe anoxic, metabolic, or traumatic brain injury, and has been in this condition for over a month. Neuropathologic findings in anoxic encephalopathy may include cortical pseudolaminar necrosis, cerebellar Purkinje cell loss, and necrosis of hippocampal cortex but relative sparing of brainstem structures [26]. Persistent vegetative state is considered permanent if the patient has been in this state for 3 months after nontraumatic or anoxic brain injury, and more than 12 months after traumatic brain injury [27].

**Minimally Conscious State**

These are patients who, similar to those in the vegetative state, have severely impaired consciousness, also manifest the posturing, reflexes, and diurnal cycles, but in addition show evidence of self and environmental awareness. They may follow simple commands, give gestural yes or no responses, verbalize intelligibly, and do other purposeful behaviors and visual tracking [1,13,14]. This is considered to be a transitional phase of recovery from coma after persistent vegetative state (PVS), and patients with traumatic brain injury who are in a minimally conscious state have significantly better outcomes at 1 year than PVS patients. Many publicized reports of late recoveries from
vegetative states were actually patients in minimally conscious state (MCS).
Coma in the ICU is a medical emergency. The goal of each evaluation is to identify and treat promptly (if applicable) the cause of the comatose state; even if no definitive treatment is available, general medical and neurologic support is necessary. A neurologic consultation should be obtained early; the practice of obtaining imaging studies before a careful and systematic examination is often counterproductive when it delays focused evaluation and treatment. The proper approach requires (a) immediate administration of life-support measures, (b) completion of a general physical examination, (c) performance and interpretation of the neurologic examination, (d) selection of ancillary tests, and (e) institution of definitive treatment, based on the above observations.

Initial Measures

As in all emergencies, vital signs, respiration, and circulation are first stabilized and monitored; the comatose patient often requires an endotracheal tube for respiratory support and airway protection. A large-bore intravenous line is started, and the blood is drawn for a complete blood cell count, glucose, electrolytes (including Ca\(^{2+}\)), blood urea nitrogen, creatinine, liver transaminases, and a toxicology screen. Arterial blood is obtained for determination of oxygen tension, PCO\(_2\), and pH. If there is any doubt about the etiology of coma, 100 mg thiamine, 50 g glucose, and 0.4 mg naloxone are administered intravenously.

General Physical Examination

In addition to the usual complete examination, several points warrant special attention [1,2,13]. Severe hypothermia (rectal temperature less than or equal to 32°C or 89.6°F) may cause coma (as in elderly patients exposed to the cold) or provide clues to other etiologies (e.g., overwhelming sepsis, drug or alcohol intoxication, hypothyroidism, hypoglycemia, Wernicke’s encephalopathy) [28]. Severe hyperthermia may result from intracranial causes, including infection and anterior hypothalamic or pontine destruction. Meningeal signs (e.g., nuchal rigidity) may be absent in deeply comatose patients, even in the presence of overwhelming bacterial meningitis. This sign should never be sought if cervical spine fracture or dislocation is suspected.

The skin should be thoroughly inspected for signs of trauma. Basilar
skull fractures may be signaled by blood behind the ear (Battle’s sign), cerebrospinal fluid rhinorrhea, or otorrhea. Orbital fractures may cause bleeding into periorbital tissues (“raccoon eyes”).

The breath odor may suggest metabolic derangement or intoxication. The spoiled fruit odor of diabetic coma, the uriniferous odor of uremia, and the musty fetor of hepatic encephalopathy sometimes can be recognized. Although the odor of alcohol is usually noted, its presence does not rule out superimposed structural causes of coma (e.g., subdural hematoma), and its absence does not rule out intoxication with odorless spirits (e.g., vodka).

Respiratory patterns in comatose patients are distinctive [1,13,14]. Bilateral hemispheric or diencephalic disturbances as well as systemic disorders may lead to periodic breathing in which increasing and then decreasing breaths (crescendo–decrescendo) alternate with apnea (Cheyne–Stokes respirations). Lesions of the midbrain-pontine tegmentum may give rise to tachypnea and a respiratory alkalosis unresponsive to oxygen (central neurogenic hyperventilation), but this is much less common than hyperpnea due to low oxygen tension, metabolic acidosis, or a primary respiratory alkalosis (e.g., salicylate poisoning). Lesions of the inferior pons may be associated with 2- to 3-second pauses following full inspiration (apneustic breathing). Compressive or intrinsic lesions of the medulla may cause chaotic breathing of varying rate and depth (Biot’s breathing). Complete brainstem destruction results in apnea that is unresponsive to elevated PCO₂.

Neurologic Examination

The goal of the neurologic examination in the comatose patient is to determine the location of the lesion (ARAS or bilateral cerebral hemispheres) and its etiology (structural, causing destruction or compression of brain substance; toxic, metabolic, anoxic, or traumatic, affecting the nervous system in a diffuse or multifocal manner; subarachnoid blood or infection; or nonconvulsive status epilepticus). A critical part of this determination is the medical history, and heroic efforts to locate family members, witnesses, and medication lists are almost always rewarded. For example, truly sudden coma in a healthy person suggests drug intoxication, intracranial hemorrhage, meningoencephalitis, or an unwitnessed seizure.

Often an intubated patient with altered mental status will be on pharmacologic sedation or anxiolysis for management of respiration, or safety in agitated or combative patients. Neurologic examination should
be performed after discontinuing any sedating medication that may alter the patient’s responsiveness and significantly alter the examination findings.

Neurologic assessment must include a description of the level of consciousness, examination of the pupils, direct ophthalmoscopy, observation of spontaneous and induced ocular movements, elicitation of the corneal reflex, and tests of motor system function (including spontaneous and induced limb movements and asymmetries of tone), deep tendon reflexes, pathologic reflexes, and response to sensory stimulation—often pain. The importance of repeat examinations to document the temporal course of the patient’s condition cannot be overemphasized.

Level of Consciousness

The level of consciousness is determined first by observing the patient undisturbed for several minutes. Any spontaneous (e.g., yawning, sneezing) or responsive (e.g., to ventilator noise) movements or postures are noted. A battery of graduated sensory stimuli is applied (whispered names, shouted names, loud noise, visual threat, noxious stimulation by supraorbital compression, vibrissal [nasal hair] stimulation, sternal rub, nail bed compression, or medial thigh pinch) and the response recorded (e.g., opens eyes, squeezes eyes shut, blinks symmetrically to visual threat, nods, turns head, groans, grimaces, purposefully withdraws, displays stereotyped posturing). Initially using centrally located noxious stimulation such as a sternal rub is important in order to tell if the patient is localizing or merely withdrawing. Such careful documentation allows serial assessments of subtle changes over time by multiple examiners.

Serial documentation and accurate and reliable communication of findings can be facilitated by the use of standardized scales such as the Glasgow Coma Scale. Although originally intended for use in traumatic brain injury, the Glasgow Coma Scale has become widely used and has been found to be predictive of outcomes, particularly in traumatic brain injury (Table 145.4). Because of its limitations, a more comprehensive coma scale called the Full Outline of Unresponsiveness, or FOUR score, incorporates brainstem reflexes and respiration [1,13,14,29] (Table 145.4). These grading scales are helpful to standardize assessment, improve communication and serial monitoring, but are limited and cannot be substituted for a detailed bedside neurologic examination.

Pupils

The pupils are examined for size, equality, and reactivity to light. Normal pupils confirm the integrity of a circuit involving the retina, optic nerve, midbrain, third cranial nerve, and pupillary constrictors. A strong flashlight and magnifying glass, or an ophthalmoscope, are usually necessary, and darkening the room is helpful. In difficult cases, sometimes pupillometry can be employed.

Symmetrically small, light-reactive pupils (miosis) are normally seen in elderly and sleeping patients. Opiates, organophosphates, pilocarpine, phenothiazines, and barbiturates produce small pupils that may appear to be unreactive to light, whereas a large lesion of the pons (i.e., hemorrhage) characteristically produces tiny pinpoint pupils. Symmetrically large pupils (mydriasis) that do not react to light suggest midbrain damage, but they may also be seen following resuscitation when atropine has been used (in this case, the pupils do not constrict to 1% pilocarpine) [30], in cases of anoxia, following pressor doses of dopamine [31], and often in amphetamine or cocaine intoxication. Bilaterally fixed and midposition pupils indicate absent midbrain function, although severe hypothermia [28], hypotension, or intoxication with succinylcholine [32] or glutethimide [33] must be ruled out.

Pupillary asymmetry (anisocoria) suggests neurologic dysfunction if it is of recent onset, the inequality is more than 1 mm, and the degree of anisocoria changes with ambient lighting [34]. When the larger pupil is sluggishly reactive or fixed to light (but the contralateral consensual response is spared), uncal herniation due to an ipsilateral hemispheric mass compressing the third cranial nerve against the petroclinoid ligament must be considered. Unilateral pupillary dilatation may also indicate a mass in the cavernous sinus, aneurysm of the posterior communicating artery, focal seizure, or topical atropine-like drugs (e.g., used for ophthalmoscopic examination). On the other hand, with Horner’s syndrome, the affected pupil is smaller. In this condition, the pupillary asymmetry is increased in darkness and the smaller pupil is associated with partial ptosis of the upper eyelid, straightening of the lower eyelid, and facial anhidrosis. It may be caused by damage to descending sympathetic fibers anywhere from the hypothalamus to the upper thoracic cord, or to ascending sympathetic fibers in the cervical sympathetic chain, the superior cervical ganglion, the carotid artery, or the cavernous sinus.
Measuring the neurologic pupil index (NPI) with a pupillometer can facilitate assessment in situations when pupil assessment is clinically difficult and changes in the NPI can be an early indicator of increased intracranial pressure [35].

Direct Ophthalmoscopy

Direct ophthalmoscopy may be limited by miosis or cataracts, but the pupils should never be pharmacologically dilated without clear documentation (with a large sign taped to the patient’s bed), or if the patient’s condition is uncertain or unstable. Obscuration of the disk margins, absent venous pulsations, and flame-shaped hemorrhages suggest early papilledema from an intracranial mass or systemic hypertension [36]. Subhyaloid and vitreous hemorrhages may be observed in the patient with subarachnoid hemorrhage or suddenly increased intracranial pressure.

Ocular Movements

Assessment of ocular movements begins by observing for tonic deviation of the eyes at rest [1]. The eyes may deviate toward the side of a lesion in the motor cortex (a gaze preference—away from the hemiparetic limbs) but usually can be induced to cross the midline. The eyes deviate away from the side of a pontine lesion (toward the hemiparetic limbs) and cannot be moved across the midline (a gaze paralysis). A seizure focus in the frontal (area 8) or supplementary motor (area 6) cortex can drive the eyes or cause nystagmoid jerks contralaterally (toward the side of the convulsing limbs) [37]. Tonic upward eye deviation may be seen after anoxia [38], and tonic downward deviation may be seen in thalamic hemorrhage, midbrain compression, and hepatic encephalopathy. Spontaneous eye movements may have a localizing value. Roving eye movements (slow and random, usually conjugate and horizontal) and periodic alternating (“Ping-Pong”) gaze (cyclic, conjugate excursions to the extremes of lateral gaze every 2 to 3 seconds) [39] are found in patients with intact brainstem function. Ocular bobbing consists of a rapid conjugate downward jerk followed by a slow upward drift (rate and rhythm are variable) and suggests a lesion in the pons or posterior fossa, especially if horizontal eye movements are impaired [40]. The reverse movement, ocular dipping (slow downward, fast upward), can also be seen less reliably in pontine lesions but also after anoxia and in status epilepticus [41]. Conjugate spasmodic eye movements, rotating the eyes upward for minutes or longer (oculogyric crisis), in some patients may be an untoward effect of neuroleptic medications.

If spontaneous eye movements are absent or restricted to a particular
direction, reflex movements should be tested by oculocephalic (“doll’s eyes”) and oculovestibular (caloric) stimulation [1,17,18,42]. Full eye movements induced by these maneuvers confirm the integrity of the brainstem tegmentum from the medullary–pontine junction to the midbrain. Oculocephalic testing is never done in patients with suspected cervical spine fracture or dislocation. The maneuver is performed by holding the patient’s eyelids open and briskly rotating the head from one side to the other (for horizontal eye movements) and from flexion to extension (for vertical eye movements). In comatose patients with an intact brainstem, the eyes deviate to the side opposite the direction of head movement. If the oculocephalic response is not obtained or the movements are limited or asymmetric, the oculovestibular reflex should be tested. This is never done until the tympanic membrane is examined and seen to be intact. The patient’s head is elevated to 30 degrees above horizontal, and up to 120 mL ice water is instilled slowly in the external auditory meatus with a large syringe and attached Teflon catheter. Each ear is tested separately for horizontal eye movements, with a 5-minute interval between right and left ears. In awake patients (or those in psychogenic coma), nystagmus with the fast phase away from the irrigated ear is induced. In comatose patients with an intact brainstem, a tonic conjugate eye deviation toward the irrigated ear is seen; a defective response implies brainstem damage. Vertical eye movements can be induced by irrigating both ears simultaneously with cold water (eyes deviate downward) and with warm (44°C) water (eyes deviate upward). Absent or deranged responses can be caused, in addition to various brainstem lesions, by previous vestibular (labyrinthine end-organ) lesions, vestibulosuppressant drugs (e.g., benzodiazepines, antihistamines, anticholinergics), hepatic encephalopathy, and neuromuscular blockers (e.g., succinylcholine). An ophthalmoplegia after intravenous phenytoin is well known [43].

Corneal Reflex

The corneal reflex is obtained by lightly touching the limbus of the cornea with a fine material (wisp of cotton, rolled corner of tissue paper, or a squirt of air or saline). Both eyes should blink to unilateral stimulation, confirming the integrity of a circuit involving the fifth cranial nerve, trigeminal sensory and facial motor nuclei in the pons, and both seventh cranial nerves. A blunted corneal response is commonly seen in chronic contact lens wearers. An absent blink on the stimulated side with an intact contralateral (consensual) response indicates ipsilateral motor damage.

p. 1335
Motor System

The examination of the motor system identifies whether limb movements are appropriate and purposeful or inappropriate and stereotyped. Left–right asymmetries or worsening of the motor response over time must be carefully noted. Appropriate movements include spontaneous turning in bed, drawing up the sheets, crossing the legs modestly, or rapid withdrawal (especially abduction) from noxious stimulation. Applying noxious stimuli centrally such as a sternal rub or pinching the proximal area of an arm or leg will allow distinction between localization which is purposeful and indicates intact awareness at a cortical level versus mere withdrawal which can be a brainstem reflex and this can have prognostic implications. Inappropriate movements include spontaneous or induced flexion–internal rotation of the arms with extension of the legs (decorticate posturing) or extension-adduction of all limbs (decerebrate posturing); whether flexor or extensor postures are induced depends partly on the position of the limbs [44]. These responses may occur occasionally in toxic-metabolic coma [45,46] but are more common with anatomic brainstem lesions. Facial grimaces or groans despite absent motor responses suggest that sensory pathways are grossly intact. Flexion of the leg at the hip, knee, and ankle (triple flexion response) is a spinally mediated exaggerated Babinski reflex that may persist in brain death.

Other spontaneous movements of the limbs and trunk have been observed in brain dead patients and are all forms of spinal reflexes, including myokymia, trunk flexion, and the Lazarus sign, wherein the patient actually extends and pronates his or her arms forward and then crosses them over the chest [1,17,18,47]. These signs are easily misinterpreted by family members as well as medical practitioners who are not versed in the neurologic examination.
INTERPRETATION OF THE NEUROLOGIC EXAMINATION

In general, focal neurologic signs suggest a structural cause of coma. Nevertheless, focal weakness is not unknown in hypoglycemia, hyperglycemia, hyponatremia, hyperkalemia, and rarely hepatic and uremic encephalopathies; and continuous focal motor seizures (epilepsia partialis continua) may be a presenting sign of the hyperglycemic nonketotic hyperosmolar state. Focal signs due to preexisting deficits may deceive even the ablest clinician. For example, if generalized seizures from a new metabolic imbalance develop in a patient with an old hemiplegia due to a cerebral infarction, apparently focal convulsions of the nonplegic limbs might falsely suggest a structural lesion of the intact cerebral hemisphere contralateral to the previously infarcted one. Other false localizing signs include sixth nerve palsies (due to transmitted increased intracranial pressure), visual field cuts (due to compression of the posterior cerebral artery), and hemiparesis ipsilateral to a third nerve palsy (due to compression of the contralateral cerebral peduncle against the tentorium [Kernohan’s notch]).

Conversely, a nonfocal examination does not invariably indicate toxic-metabolic coma. Symmetric neurologic dysfunction may be caused by meningoencephalitis, subarachnoid hemorrhage, bilateral subdural hematomas, or thrombosis of the superior sagittal sinus. Multifocal seizures, myoclonus, asterixis, or fluctuation of the examination suggests a toxic or metabolic etiology, although periodic increases in intracranial pressure (plateau waves) and nonconvulsive seizures may lead to a waxing and waning mental status.

A preserved pupillary light reflex even in deep coma with absent oculovestibular and motor responses suggests a toxic or metabolic etiology. It is important to note that the pupils may be unreactive to light in severe hypothermia, deep barbiturate coma (the patient is usually apneic and hypotensive if the pupils are fixed), and glutethimide overdose. In addition, an expanding posterior fossa mass (e.g., cerebellar hemorrhage) may present with early signs of pontine compression and small, light-reactive pupils.

A useful rule is that toxic-metabolic coma usually has incomplete but symmetric dysfunction of neural systems affecting many levels of the neuraxis simultaneously while retaining the integrity of other functions at the same levels. Structural coma is characterized by regionally restricted anatomic defects. For example, toxic-metabolic coma might present with intact pupillary reactivity and corneal reflexes but an
absence of horizontal (pontine) and vertical (midbrain) reflex eye movements to oculovestibular testing. Such a presentation would be inconsistent with coma from a structural cause.
ANCILLARY TESTS

Imaging studies are often necessary and always informative in the patient with altered consciousness to shed light on the etiology or structural contributors to the patient’s clinical presentation, but require interpretation specific to the patient’s clinical data and examination. Neuroanatomic correlation of imaging and examination are essential in their use and also provide useful prognostic information. A computed tomographic (CT) scan can be considered the initial brain imaging study in patients with coma if lesions that require emergent surgical intervention, such as acute cerebellar hemorrhage, are considered [1,13,14]. A CT scan without contrast infusion can reliably demonstrate intracranial bleeding such as intraparenchymal, epidural or subdural hematoma, or intraventricular hemorrhage. CT scans can reveal hydrocephalus; and may show anoxic–ischemic brain injury, with loss of gray–white differentiation, border-zone infarction from hypoperfusion, and diffuse cerebral edema (Fig. 145.2). Other coma-inducing lesions shown by CT scan include massive middle cerebral infarction, uncal herniation, and midline shift from large mass lesions with cerebral edema. Contrast enhancement may be required for suspected infectious or neoplastic masses. The CT scan does not reliably rule out inflammation, infection, subarachnoid blood, or early ischemia. CT angiography can be helpful in showing large vessel occlusion or dissection but has limited sensitivity and specificity.

**FIGURE 145.2** Noncontrast CT scan of patient with anoxic brain injury. Diffuse cerebral edema with loss of gray–white differentiation, obliteration of basal cisterns, multiple areas of hypodensity suggestive of anoxic–ischemic injury, and venous stasis with hyperdensity of the venous sinuses. This patient was brain dead clinically and by apnea testing.
Magnetic resonance imaging (MRI) is clearly superior to CT scan in resolution, and special sequences are highly sensitive to acute ischemia and encephalitis. MRI is superior for anatomic detail and can produce excellent images of the posterior fossa, brainstem, and craniocervical junction. Diffusion weighted MRI studies, and particularly whole brain median apparent diffusion coefficient imaging, is useful in assessing prognosis following anoxic–ischemic coma [52–54]. Although it is not always logistically possible to perform MRI imaging on patients in the ICU, whenever possible it provides important information.

New developments and research using functional magnetic resonance imaging (fMRI) are not only shedding light on the importance of specific structures to consciousness, and other clinical states such as abulia, but are also furthering our understanding of the importance of connectivity [55] and specific circuits to coma. (Fig. 145.3). Numerous studies in patients with persistent vegetative and minimally conscious states show activation in the primary auditory cortex and higher order temporal lobe areas when their names are spoken to them by familiar voices. Other speech comprehension tasks in which the level of activation is highest in patients who improved from PVS to MCS suggest the possibility of a new frontier in clinical understanding of coma, and clinical utility in prognostication [56,57].

FIGURE 145.3 Anatomic substrates of arousal
and awareness. Consciousness involves two main components: arousal and awareness of oneself and of the environment. Awareness is dependent on the integrity of specific anatomic regions. The ascending reticular activating system (ARAS), the primary arousal structure, is located in the upper pons and lower midbrain in the posterior part of the upper two-thirds of the brainstem. A ventral pathway (black solid arrows) projects to the hypothalamus (hypo) and basal forebrain (Bfb); a dorsal pathway (black dashed arrows) projects to the reticular nuclei of the thalamus (thal); and a third pathway (light gray arrows) projects directly into the cortical regions. From the basal forebrain, two main bundles project diffusely to several cortical areas. The reticular nuclei of the thalamus connect to other nuclei in the thalamus. They are involved in a thalamocortical circuit that controls cortical activity. Some regions of the cerebral cortex may also make specific contributions to consciousness.

The cerebrospinal fluid must be examined if meningoencephalitis is suspected or if subarachnoid blood is not visualized on the CT scan. Occasionally, a sterile cerebrospinal fluid pleocytosis follows status epilepticus [58]. The cerebrospinal fluid sent for protein 14–3-3, or tau protein, may also be useful in the diagnosis of CJD. Cytology and vascular endothelial growth factor levels can confirm the diagnosis of carcinomatous meningitis; and antibodies can be evaluated in paraneoplastic syndromes such as limbic encephalitis.

EEG provides a physiologic marker of brain function and may be helpful in nonconvulsive status epilepticus and psychogenic coma, and for documenting (but not primarily establishing) brain death by the presence of electrocerebral silence. Current research correlates EEG background patterns with fMRI and positron emission tomography scans in response to speech comprehension tasks, and investigates the utility of EEG for prognostication in patients with altered consciousness [59].

In unresponsive patients, somatosensory or brainstem auditory evoked potentials may be very useful in evaluating the integrity of spinal, brainstem, or cortical pathways and, compared to EEG, are much less susceptible to drug effects and hypothermia. SSEPs are useful in prognostication of recovery from anoxic–ischemic coma during the first few days after cardiac arrest.
Definitive treatment of altered consciousness depends on the underlying pathophysiologic process, but urgent therapeutic interventions may be required in life-threatening conditions or to prevent further central nervous system insult. Meticulous nursing care (fluid replacement, oxygenation and prevention of aspiration, nutrition, corneal protection, and conscientious skin, bowel, and bladder care) is essential. Unnecessary sedation should be avoided—it obscures evaluation of the patient’s state of consciousness and makes assessment of any changes in the sensorium or cognition inaccessible to testing.

Recent and ongoing clinical trials are continuing to validate acute therapies that may protect the brain after insults such as cardiac arrest, traumatic brain injury, and stroke. For example, the induction of mild hypothermia (33°C for 12 to 24 hours) in comatose survivors of cardiac arrest improved the neurologic outcome in two randomized clinical trials [60,61]. Based on these studies, the American Heart Association and the International Liaison Committee on Resuscitation advised therapeutic mild hypothermia for unconscious victims of cardiac arrest [62]. Hypothermia appeared ineffective as an acute treatment for traumatic brain injury in one large randomized controlled trial [63] but may have been related to the delay in achieving goal temperature, duration of cooling, as well as other factors. A recent systematic review of 12 randomized controlled trials that pooled 1,069 patients concluded that clinical mortality and outcome benefit may be derived from cooling patients with traumatic brain injury to a temperature of 32°C to 33°C for 48 hours and slowly rewarming them 24 hours after discontinuation of therapy [64]. A multicenter trial of early induced hypothermia for severe traumatic brain injury for 48 hours failed to show benefit, but was terminated prematurely and was confounded by intracranial hypertension during rewarming [65].

A more recent clinical trial of therapeutic hypothermia (33°C) versus normothermia (36.5°C) in children who remained unconscious after out-of-hospital cardiac arrest again showed no benefit in survival with good functional outcome at 1 year [66]. Despite several failed clinical trials, there remains a physiologic basis for its use, and there is still some interest in hypothermia and its effects on edema and intracranial pressure. However, the challenges of achieving therapeutic hypothermia and multiple complications including cardiac arrhythmia, coagulopathy, and infection, as well as complications of rewarming have hindered significant progress in its utility [67,68]. Many guidelines are now adapting a more conservative targeted temperature management
protocol which includes an option for goal temperature of 36°C rather than the previous 32°C to 34°C [69,70]. If patients sustaining a neurologic insult are hypothermic upon admission to the ICU, it may be prudent to avoid aggressively warming them to normothermic levels. The benefit from mild hypothermia likely involves more complex biochemical mechanisms than simple reduction in oxygenation requirements. The deleterious effects of fever in brain injury are well documented in the laboratory and clinical outcome studies in a variety of diseases [71]. No large studies have prospectively addressed the effects of induced normothermia on outcomes. Comparison of endovascular and standard normothermia protocols to achieve a temperature of 36.5°C found no increase of adverse events, but was underpowered to show any benefit on neurologic outcomes [72]. Further study in a larger sample of patients is warranted, and the development of protocols to control fever or induce normothermia is expected to benefit these patients.
CONCLUSION

Altered consciousness is common in patients in the ICU. A systematic and efficient approach is required to determine the location of the responsible lesion(s) or the cause(s) of impaired consciousness, both to allow institution of definitive therapies and to assess the prognosis accurately.

6. Seibert DG: Reversible decerebrate posturing secondary to

Metabolic encephalopathy is a general term used to describe any process that affects global cortical function by altering the biochemical function of the brain. It is the most common cause of altered mental status in the intensive care unit (ICU) setting, either medical or surgical, and is also one of the most treatable. Early recognition of metabolic encephalopathy, therefore, is critical to the management of the ICU patient. The patients who are most at risk for development of a metabolic encephalopathy are those with single or multiple organ failure, the elderly (>60 years of age), those receiving multiple drugs with central nervous system (CNS) toxicity, and those with severe nutritional deficiencies such as cancer patients and alcoholics. Other risk factors include infection, temperature dysregulation (hypothermia or fever), chronic degenerative neurologic or psychiatric diseases such as dementia or schizophrenia, and endocrine disorders. Metabolic encephalopathy is always suspected when there is an altered cognitive status in the absence of focal neurologic signs or an obvious anatomic lesion such as an acute cerebrovascular accident or head injury. A patient may progress over days from intermittent agitation into depressed consciousness or quickly into coma without any antecedent signs (e.g., with hypoglycemia). In mild cases, it is easily mistaken for fatigue or psychogenic depression, whereas more severe cases may develop into coma and are life-threatening.

The altered mental status observed can start as mild confusion with intermittent disorientation to person, time, or place and difficulty attending to questions or tasks at hand. Delirium is a further change toward heightened arousal alternating with somnolence, often worse at night and fluctuating throughout the day. Finally, progression to lethargy, a state of sleepiness in which the person is difficult to arouse by vigorous stimulation, can lead into stupor or coma as impaired consciousness ensues. This sequence of events is often punctuated by focal or
generalized tonic–clonic seizures and postictal somnolence as part of the overall clinical picture (Table 146.1).

CNS, central nervous system.

Disorders that can be confused with metabolic encephalopathy include brain tumors, encephalitis, meningitis, closed head trauma, and brainstem cerebrovascular events. Brain tumors are usually recognizable because they produce focal neurologic deficits such as hemiplegia or hemianopsia, as do traumatic lesions of the brain and cortical strokes. Hypoglycemia can also present focally and is discussed further in the section on Hypoglycemic Encephalopathy. Brainstem stroke due to thrombosis of the basilar artery can be deceptive because there may be a gradual progression of signs and symptoms over several hours rather than a sudden presentation. Table 146.2 outlines some of the cardinal differences between brainstem stroke and metabolic encephalopathy.

## EVALUATION

### Clinical Examination

Initial observation of the patient’s level of arousal, posture in bed, breathing pattern, vital signs, and behavioral fluctuations is highly suggestive of a metabolic disturbance in many cases. Waxing and waning levels of activity are the hallmark of metabolic encephalopathy and may occur over hours to days. Often signs of sympathetic overactivity (tachycardia, elevated blood pressure, tremulousness) and abnormal sleep patterns or “sun-downing” are present.

Mild *behavioral changes* are the earliest manifestations, such as lack of attentiveness to surroundings or a paucity of spontaneous speech, which may give the patient an apathetic or withdrawn appearance. The Mini-Mental State Examination easily reveals mild confusion and can be used to grade the patient’s level of cognitive performance sequentially [1]. When there is impaired consciousness, however, this test is unreliable.

The *cranial nerve examination* is focused on pupillary responses, oculomotor function, and respiratory patterns (Table 146.3). As a rule, pupils are small, symmetric, and responsive to light in metabolic causes of obtundation or coma. Noteworthy exceptions to this are anticholinergic poisoning (e.g., atropine, scopolamine), which produces dilated sluggish pupils, and glutethimide (Doriden) poisoning, which results in mid- to large-sized sluggish or fixed pupils [2]. Ocular
movements are usually unaffected initially, with eyes in midline position or slightly deviated outward and upward at rest (Bell’s phenomenon). Doll’s eye maneuvers produce conjugate deviation of the eyes opposite to the direction of head rotation. As the level of brainstem suppression progresses to coma, these responses may disappear completely, especially with an overdose of sedative drugs. In the face of hyperpnea and decerebrate rigidity, the preservation of doll’s eyes is a useful sign pointing to a metabolic, rather than anatomic, cause of coma.

Changes in the respiratory pattern are the next most important finding for the diagnosis of metabolic encephalopathy, also providing a clue as to its etiology. In the mildly confused patient, breathing may be normal, but lethargic or mildly obtunded patients tend to hyperventilate, with brief spells of apnea. This is due to transient lowering of the partial pressure of carbon dioxide (PCO₂) below 15 mm Hg without the appropriate CNS drive to breathe more rapidly at a lower tidal volume. After 12 to 30 seconds of apnea, the cycle of hyperventilation appears

Changes in the respiratory pattern are the next most important finding for the diagnosis of metabolic encephalopathy, also providing a clue as to its etiology. In the mildly confused patient, breathing may be normal, but lethargic or mildly obtunded patients tend to hyperventilate, with brief spells of apnea. This is due to transient lowering of the partial pressure of carbon dioxide (PCO₂) below 15 mm Hg without the appropriate CNS drive to breathe more rapidly at a lower tidal volume. After 12 to 30 seconds of apnea, the cycle of hyperventilation appears
again, resulting in a pattern of “periodic respirations” [3]. Hypoventilation is usually seen with depressant drug overdoses, chronic pulmonary failure, and metabolic alkalosis of any cause. Cheyne–Stokes respiration, a rhythmic cycle of waxing and waning hyperpnea/apnea, is another pattern that is occasionally seen in metabolic encephalopathy caused by uremia or hypoxia, but more commonly this indicates bilateral structural lesions of the cortex. Other neurogenic respiratory patterns, such as constant or “central” neurogenic hyperventilation, cluster breathing, and ataxic breathing, are signs of brainstem dysfunction due to structural damage or suppression by barbiturates. These changes are seen only when the patient is stuporous or comatose.

Abnormal motor activity is characteristic of many metabolic encephalopathies and is quite varied in appearance; tremors, myoclonus, asterixis, rigidity, and choreoathetosis may be seen. Tremors are rhythmic, involuntary oscillatory movements seen in all limbs and often exaggerated during voluntary movement. Tremors occur most often in early hypoglycemic encephalopathy, thyrotoxicosis, acute uremia, chronic dialysis encephalopathy, hypercapnia, and drug intoxication, especially with sympathomimetic agents. Myoclonus is multifocal, appearing as brief shock-like contractions of large muscle groups. Synchronous myoclonic jerks in all limbs can be seen in any patient who is slipping in and out of a drowsy sleep—also known as sleep-onset myoclonus. This is often seen in patients who are receiving large doses of narcotics. Multifocal myoclonus, in contrast, is seen in hypoxic–ischemic encephalopathy, chronic hepatic failure of all types, uremia, pulmonary failure, and intoxication with methaqualone and psychedelic agents [4].

Asterixis is a flapping movement produced by unsustained muscle contractions against gravity. Rhythmic extension and flexion of the outstretched limb is present, which disappears at rest. The most common setting for this is in hepatic encephalopathy of any cause, frequently with flapping of the hands, feet, jaw, and tongue. Subacute uremia and pulmonary failure produce asterixis accompanied by myoclonus, which presents a picture of almost constant muscular jerking movements. Rigidity or generalized muscle spasms are states of constant muscle contraction that are seen when the degree of metabolic encephalopathy is more severe and leads to stupor or coma. This can be the result of end-stage hepatic failure, hypoglycemia (<25 mg glucose per dL) lasting more than a few minutes, acute renal failure, hyperthermia, and hypothermia below 92°F rectally. Rigidity with dystonic posturing is a clue to
amphetamine or phenothiazine poisoning. Choreoathetosis, on the other hand, occurs in chronic hepatic failure, subacute bacterial endocarditis, posthypoxic insult, Reye’s syndrome, chronic dialysis, chronic hypoglycemia, and chronic hyperparathyroidism, appearing as a nonpatterned sequence of twisting or dance-like limb movements.

The reflex examination often reveals diffuse hyperreflexia, symmetric except in limbs that were previously affected by a structural lesion. Plantar responses, also known as the Babinski reflex, are typically extensor in both feet and can be elicited easily. In contrast, the sensory examination is usually not affected, but is unreliable if the patient is agitated or obtunded. Response to pinprick, painful pinch/pressure, or a cold stimulus on the limbs is the most useful in demonstrating a grossly intact sensory arc.

Abnormal autonomic responses in metabolic encephalopathy may demand intervention and can cause significant morbidity and mortality. Hypotension, unresponsive to volume expansion, points to intoxication with barbiturates or opiates, myxedema, or Addisonian crisis. In this setting, occult sepsis must always be ruled out before treating for specific metabolic derangements. Fever and leukocytosis may be absent in very debilitated patients. Examination of urine, blood cell counts and coagulation factors, blood and sputum cultures, chest x-ray, and a lumbar puncture are essential to rule out infection. If there remains any doubt about the cause of hypotension, empiric antibiotics, naloxone hydrochloride (Narcan) for possible opiate overdose, intravenous (IV) glucose (one ampoule), and vasopressor should be added to other supportive measures acutely while the cause is being investigated.

Seizures are another significant symptom of metabolic encephalopathy, especially in uremia, hypoglycemia, pancreatic failure, and various types of metabolic acidosis (e.g., ethylene glycol, salicylates, and so forth). They occur most often at the onset of the metabolic disturbance, for example, as the blood urea nitrogen (BUN) is climbing acutely, and as a preterminal expression of severe neuronal injury in a comatose patient. Management of the seizures is typically ineffective until the underlying cause is corrected. In renal failure, however, one-third to half of the standard loading doses of phenytoin or phenobarbital may be all that is needed to control seizures. The interictal electroencephalogram (EEG) serves as a guideline to the need for continued treatment once the encephalopathy has cleared or has become chronic and stable. A persistent focus of epileptiform activity on the recording warrants further investigation and anticonvulsant therapy.
The laboratory investigation of patients with delirium or coma is crucial in defining the cause of a metabolic encephalopathy. Blood tests for glucose, electrolytes, and blood gases should be drawn immediately along with a panel of hepatic function tests (ratio of serum alanine aminotransferase to serum aspartate aminotransferase, lactate dehydrogenase, ammonia [NH₄⁺]), BUN, and creatinine. Serum and urine osmolality, cerebrospinal fluid (CSF) analysis, serum magnesium and phosphate levels, and specific hormone levels may be needed to define the cause of encephalopathy further. Careful review of all medications taken before and during hospitalization may direct attention to toxicology screens of blood and urine. The general toxicology screen should be sensitive to opiates, benzodiazepines, caffeine and salicylates, theophylline, barbiturates, and alcohol. Additional drug levels should be ordered if their use is known or suspected (e.g., digoxin, cocaine, phenytoin, and so forth). If there has been a sudden change in mental status, a bolus of 25 g glucose should be administered intravenously without hesitation to avoid prolonged hypoglycemia.

Pharmacogenomic studies have revealed that there are 58 genetic variants in metabolic pathways that play a significant role in drug metabolism and activity at target sites, thus influencing toxicity. The most significant of these are Cytochrome P450 (CYP) 3A9 and CYP2D6 which can be overexpressed (ultrarapid metabolizers), underexpressed (poor metabolizers), or normal. Many selective serotonin reuptake inhibitors and cardiovascular agents are metabolized by these two classes of enzymes and the aforementioned variants may cause drug levels to be too high or to be converted to active forms so quickly that peak levels are higher than expected, contributing to the adverse effect profiles. Poor metabolizers may also have more drug–drug interactions because of competitive inhibition of clearance of one drug versus the other when coadministered. Reference lists for problematic pharmacogenomic effects are updated regularly and widely available on websites for pharmacologists and toxicologists. General availability of testing for cytochrome P (CYP) variants is limited currently but may become important in the near future in screening for drug-induced encephalopathy as the technology becomes less expensive and quicker.

In general, the EEG in metabolic encephalopathy is abnormal; background slowing is the most common pattern found (<9 Hz) [5]. Other patterns can also be useful in identifying or corroborating the cause of the encephalopathy. Slow activity that is prominent frontally, with deep triphasic waves (in the 2- to 4-Hz range), is characteristic of hepatic encephalopathy but can be seen in renal failure too [6]. This has also been reported in levetiracetam toxicity [7], hyperammonemic states due to gastroplasty [8] and ureterosigmoidostomy [9], and rare metabolic disorders such as ornithine transcarbamylase deficiency [10]. Spreading
of the slow activity toward the occipital leads is a sign of deepening coma in this setting. Bursts of high voltage activity amidst normal background frequencies are also a sign of diffuse metabolic disturbance. More importantly, the EEG in a patient with an acute encephalopathy of unknown cause may reveal subclinical (electrical, non-convulsive) status epilepticus, warranting urgent and aggressive anticonvulsant treatment. This is particularly common in the case of alcoholics and diabetics, who are at risk of multiple CNS insults.

**Neuroimaging** (computed tomography [CT] or magnetic resonance imaging [MRI]) scans are often crucial in situations in which there is rapid deterioration of mental status without focal signs or an obvious metabolic cause such as hypoglycemia. Most mass lesions, such as subdural hematomas or brain tumors, are evidenced clinically by a rostrocaudal progression of neurologic signs. The initial picture may be nonfocal with obtundation, but this is followed sequentially by flexor or extensor posturing on one or both sides and then the loss of pupillary or caloric responses. Later, medullary respiratory patterns or bradycardia appear. A noncontrast head CT or MRI is definitive in many cases but does not always distinguish a brainstem stroke. Early consultation by a neurologist is crucial, especially when the cause of impaired consciousness is not clearly due to a metabolic disorder. Transient changes in vascular permeability associated with Wernicke’s encephalopathy can manifest as vasogenic edema in the brainstem periaqueductal and fourth ventricular areas along with contrast enhancement of the mammillary bodies [11] on brain MRI.

**Lumbar puncture** is also indicated when there is a rapid onset of encephalopathy, especially with a fever, headache, or meningismus. Occult subarachnoid hemorrhage, infection, or elevated intracranial pressure may be found in the absence of funduscopic changes or clear-cut clinical history. Ideally, the lumbar puncture should be performed atraumatically with a small (22-gauge) spinal needle and a simultaneous sample of serum obtained to compare glucose and protein levels in the blood and CSF.
ETIOLOGY

Hepatic Failure

The clinical onset of hepatic encephalopathy may be subtle, with a blunting of affect and lethargy, or dramatic in 10% to 20%, with mania or an agitated delirium [12]. It is easy to recognize hepatic encephalopathy in an individual with the obvious stigmata of chronic liver disease, such as ascites, varices, or jaundice. In those without apparent liver disease, the mental changes may only appear after an additional metabolic demand on the liver. Such stressors are a high-protein meal, gastrointestinal bleeding with increased blood absorption from the gut, or hepatically metabolized drugs [13]. Sedatives and acetazolamide are particularly offensive in this situation.

Asterixis is the next most common clinical sign, appearing in all limbs, the jaw, and the tongue. As the patient progresses into a coma, asterixis may be replaced by muscle spasticity and decorticate or decerebrate posturing to stimulation. The Babinski responses are present (extensor plantar reflexes), and gaze-evoked ocular movements are variable at this stage; pupillary responses are always preserved. Oculocephalic and vestibuloocular (caloric) responses remain until the patient is moribund. Hyperventilation is another consistent sign of hepatic encephalopathy and results in respiratory alkalosis. The ocular, pupillary, and respiratory patterns above help to distinguish severe hepatic encephalopathy from space-occupying lesions of the cortex and brainstem.

The pathophysiology of hepatic coma is not certain, but it is thought to be caused by portacaval shunting of neurotoxic substances. These putative toxins include excess ammonia, large molecules normally excluded by the blood–brain barrier [14], increased water, and the “false” neurotransmitter octopamine [15]. Hypoglycemia, as a result of decreased glycogen stores in the liver, may complicate the CNS picture.

The serum transaminases are usually elevated two- to threefold, and serum ammonia is at least in the high normal range once the patient is lethargic—with a linear correlation thereafter between higher laboratory values and lower cognitive state. The CSF remains normal until the serum bilirubin exceeds approximately 5 mg per dL, which tints the fluid yellow. The EEG characteristically shows progressive slowing from the frontal to the occipital leads as coma deepens. Triphasic waves are seen in most cases but are not pathognomonic.
Therapy for hepatic encephalopathy is directed toward decreasing the amount of toxic substances that are being shunted to the brain. Neomycin and lactulose help to sterilize and flush the gut. A protein-restricted diet and the exclusion of heptatically cleared drugs decrease the metabolic load, and IV glucose effectively maintains the serum glucose level. Neurologic recovery then depends on the capacity of the liver to regenerate at least 25% of its full function. With prolonged or repeated bouts of hepatic coma, there may be persistent, irreversible signs of basal ganglia dysfunction evidenced by chorea, postural tremors, or a parkinsonian picture (acquired hepatocerebral degeneration) [16].

Reye’s Syndrome

Reye’s syndrome is a unique and quite morbid form of acute hepatic encephalopathy seen in children, usually between ages 1 and 10 years. It occurs in the clinical setting of an acute viral infection, for example, chickenpox or influenza A or B, plus aspirin therapy [17]. Approximately 4 to 7 days after the viral symptoms start, the child becomes irritable, with vomiting and sometimes with headache or blurred vision. An agitated delirium, combativeness, and progressive obtundation rapidly ensue over hours, followed by hyperventilation, pupillary dilatation, and generalized seizures. Later in the course, decerebrate rigidity, Babinski responses, and papilledema may develop as well.

The pathology of Reye’s syndrome includes infiltration of the liver and other visceral organs with small fat droplets and diffuse cerebral edema. In cases that are complicated by severe hypoglycemia and seizures, anoxic damage with laminar necrosis of the cerebral cortex is also found. The cause of these changes is presumed to be mitochondrial poisoning, but the pathogenic agent has not yet been identified. Acetylsalicylic acid has consistently been implicated in this cellular damage. This has led to the standard practice of prescribing acetaminophen instead of aspirin for viral symptoms in children, notably reducing the incidence of Reye’s syndrome [17].

The differential diagnosis relies on measurement of liver function and a high index of suspicion in the appropriate setting. The serum transaminases rise three- to fivefold in the first 48 hours, and the serum ammonia is dramatically increased, sometimes into the 200 μmol per L range. Hypoglycemia is also an early sign, aggravating the lactic acidosis and respiratory alkalosis that are seen later in the course.

Treatment for Reye’s syndrome is directed toward diminishing the cerebral edema, controlling seizures, and providing adequate electrolytes and glucose for support while the liver is effectively shut down with respect to oxidative metabolism. This is best achieved in an ICU with a standard protocol for Reye’s disease using intracranial pressure
monitoring and mannitol or glycerol for reduction of intracranial pressure [18].

The prognosis in recent years has improved markedly; mortality and morbidity are now 10% to 20%, as opposed to 40% to 50% two decades ago. Factors that contribute to a poor outcome are age less than 1 year, serum ammonia levels more than five times normal at their peak, and a prothrombin time more than 20 seconds. Other negative prognostic indicators are renal failure and a very rapid progression of liver failure in the first 48 hours. Early intervention is the key to a good outcome neurologically and systemically.

Renal Failure

Uremic encephalopathy may develop acutely, be superimposed on chronic renal insufficiency, or occur as a consequence of chronic dialysis. It is often a complication of systemic diseases that independently affect the kidneys and the CNS such as collagen vascular disease, malignant hypertension, drug overdoses, diabetes, or bacterial sepsis. The clinical picture is initially variable and does not correlate directly with measures of renal failure such as BUN and creatinine.

The first sign of encephalopathy in uremia is delirium or a decrease in the level of consciousness; hyperventilation and increased motor activity follow as the patient becomes obtunded. Also, there is a high frequency of generalized convulsions at the outset and a metabolic acidosis with low serum bicarbonate. The motor component is prominent in many patients with multifocal myoclonus, hypertonus or asterixis, and tremors, together producing a picture of “tic convulsif”—as if the patient has fasciculations [19]. Oculomotor function and pupillary responses are normal, but deep tendon reflexes may be asymmetric, and focal weakness often occurs, with shifting hemiparesis during a single period of encephalopathy. The variability of focal motor signs helps to rule out a structural lesion but does not obviate the need to look for multifocal seizures in a patient with overt twitching and depressed consciousness.

Studies of the effect of uremia on neuronal function have not been able to demonstrate a direct correlation between the cognitive state and levels of BUN or with any other biochemical or electrolyte markers. The EEG, although becoming slower with higher levels of BUN, also does not correlate with mental status changes, especially in chronic uremia [20]. Hence, the pathophysiology of uremic encephalopathy is not known.

The major diagnostic differential to consider is between a hypertensive crisis and uremic encephalopathy, because malignant hypertension often leads rapidly to renal failure and neurologic signs. Evidence of papilledema, retinal vasospasm, and cortical blindness or aphasia, with a diastolic blood pressure of more than 120 mm Hg, argues strongly for a
hypertensive crisis. In contrast, a sudden rise of BUN alone is most consistent with uremic encephalopathy.

Two variants of this disorder are seen in patients on peritoneal dialysis or hemodialysis. The acute dialysis disequilibrium syndrome is seen in children more often than in adults undergoing hemodialysis with large exchanges of dialysate. A sudden shift of solutes out of the vascular compartment produces a hyperosmolar state in the brain and subsequent water resorption intracerebrally. This results in water intoxication, with florid encephalopathy within 30 to 60 minutes. Slower dialysis obviates the problem in general [21].

Dialysis dementia is insidious by comparison and is evidenced by postdialysis lethargy, asterixis, myoclonus, dysphasia, and progressive loss of cognitive abilities over years. This disorder has been linked to increased amounts of aluminum in the dialysate augmented by aluminum-containing antacids in the diet [21]. Although the brains of patients with this disorder do not contain excess aluminum compared to those of other dialysis patients, elimination of aluminum from these sources helps reverse the symptoms in the early stages. This syndrome is now relatively rare.

The body’s response to sepsis and its pathophysiologic response to infection can include encephalopathy ranging from decreased attention, to disorientation and even to coma [22]. Sepsis-associated encephalopathy (SAE) is a transient and reversible brain dysfunction, occurring when the source of sepsis is outside the central nervous system [23]. Defining SAE must logically exclude patients with CNS insults such as TBI, CNS infection, or stroke, to name a few [22]. Some argue it is important to distinguish between altered consciousness due to shock or hypoxemia also caused by sepsis; however, it can also be argued that this is one of the mechanisms sepsis can cause encephalopathy, thus including it in the definition of SAE [24]. Inflammatory signals reach the brain via the vagal nerves stimulating medullary autonomic nuclei and the circumventricular organs that allow transport of inflammatory mediators into the brain. Thus, different areas, ranging from the brainstem to the frontal cortex, can be affected. Three major processes are thought to occur centrally. The first is neuroinflammation mediated by microglia as well as astrocytes. It is thought that this inflammation can lead to oxidative stress and mitochondrial dysfunction. Furthermore, it can cause a second process, which is the buildup of glutamate secondary to decreased removal by astrocytes. This causes apoptosis due to excitotoxicity. The third process is thought to be ischemic in nature. It is thought that sepsis and inflammation leads to macro- and microcirculatory dysfunction as well as neurovascular uncoupling, which lead to ischemia. SAE can have EEG findings ranging from theta rhythm to delta rhythms to triphasic waves or even burst suppression. Imaging
with MRI can be normal or show focal findings such as white matter hyperintensity or ischemic stroke [23]. The incidence of SAE varies widely between studies and can occur at any time during the illness. One study by Feng et al. found 42.3% incidence among patients in the ICU with sepsis. They also found higher early mortality among septic patients with SAE and higher 28-day and 1-year mortality with an RR of 2.868 (95% CI, 1.73 to 4.754). SAE was found to be correlated with E. coli sepsis, higher lactate, higher AST, lower WBC, and lower PaO₂/FiO₂.

Interestingly, there was no difference in quality-of-life indicators among sepsis survivors with or without SAE [22].

### Pulmonary Failure

A combination of hypoxemia and hypercarbia can produce typical changes of a metabolic encephalopathy in patients with underlying pulmonary failure. Individuals with chronic obstructive pulmonary disease, for example, tolerate a PCO₂ of 50 to 60 mm Hg without mental status changes. However, a sudden increase of PCO₂ of up to 65 to 70 mm Hg due to hypoventilation, or impaired oxygen exchange, can lead to lethargy, headaches, and a rise in intracranial pressure. Associated signs are papilledema or retinal vein congestion, extensor Babinski signs, asterixis, myoclonus, and often, generalized tremors. Seizures are rarely seen, and pupillary and oculomotor functions are preserved unless there is a concomitant hypoxic–ischemic insult [25].

This course of events may be precipitated by systemic infection with fatigue of ventilatory muscles, paralysis of these muscles by neuromuscular disease or Guillain–Barré syndrome, and sedative drugs with their depressant effect on the medullary respiratory center. In the well-compensated hypercarbic individual, oxygen therapy may be counterproductive by decreasing respiratory drive from the medulla. Rapid correction of hypercarbia by artificial ventilation exacerbates the compensatory chronic metabolic alkalosis that these patients have, possibly resulting in a further depression of mental status plus seizures [26].

The critical factor in the development of pulmonary encephalopathy is a rapid increase in serum PCO₂. This may be complicated by the presence of sedatives, hypoxemia, cardiac failure, and renal hypoperfusion. Treatment is directed toward slow correction of hypercarbia while maintaining an adequate PO₂ and good cerebral blood flow. Prognosis for full neurologic recovery is good if the patient is not subjected to cerebral
ischemia as well.

Hypoglycemic Encephalopathy

Hypoglycemia can occur as an isolated problem or as a complication of liver failure, of tumors producing insulin-like substances, or of urea cycle defects. The most common case is that of a diabetic with an accidental or deliberate overdose of insulin or oral hypoglycemic agents. An initial insulin reaction occurs when the serum glucose drops below approximately 40 mg per dL, producing flushing, sweating, palpitations, nausea, and anxiety. This persists for several minutes before the patient becomes confused and either agitated or drowsy [27]. Focal neurologic signs such as hemiparesis, cortical blindness, or dysphasias may appear at this point, mimicking an acute stroke [28]. If the serum glucose drops precipitously below 30 mg per dL, generalized convulsions may occur in flurries followed by a postictal coma. Prompt correction of the hypoglycemia at this point leads to reversal of the neurologic deficits, but repeated episodes can result in a subtle dementia evolving over many years [29].

When severe hypoglycemia is sustained for more than 10 minutes, stepwise progression of neurologic signs occurs. The first step is motor restlessness with frontal release signs such as sucking, grasping, and a tonic jaw jerk. Next, diffuse muscle spasms appear and sometimes myoclonic jerks. Finally, decerebrate rigidity is seen before the so-called medullary phase of hypoglycemia. The medullary phase describes a state of deep coma with dilated pupils, bradycardia, hypoventilation, and generalized flaccidity, much like hypoxic–ischemic coma. The pathologic changes associated with bouts of hypoglycemic encephalopathy are also similar to hypoxic–ischemic insults, although the cerebellum is relatively spared [30].

Differentiating hypoglycemic coma from a seizure disorder, a cerebrovascular accident, or a drug overdose is not possible at the outset unless stat serum glucose is obtained before IV fluids are administered. One should not delay treatment with a bolus of 50 mL 50% glucose (one ampoule) if there is doubt about the cause of a rapidly evolving coma, because hypoglycemic encephalopathy can result in permanent neurologic deficits if not reversed in 20 minutes or less. The first bolus of glucose must be followed by close monitoring of blood glucose levels, because most agents that lead to symptomatic hypoglycemia are long acting [31].

Hyperglycemic Encephalopathy

Hyperglycemia that is severe enough to produce mental status changes rarely occurs in isolation from other metabolic disturbances.
Hypokalemia and hypophosphatemia, hyperosmolality and ketoacidosis, or lactic acidosis often accompanies serum glucose levels more than 300 mg per dL. In contrast, acidosis may be absent in nonketotic hyperglycemic hyperosmolar states, whereas the serum osmolality is often more than 350 mOsm per kg and serum glucose more than 800 mg per dL. The neurologic changes in any case appear to correlate best with abnormalities of serum osmolality and the rate at which it is corrected [32]. In juvenile or “brittle” diabetics, ketoacidosis develops after a dose of insulin is missed or an occult infection occurs. The first changes are mild confusion, lethargy, and deep regular inspirations (Kussmaul’s breathing) in addition to signs of dehydration. Elderly patients are more prone to nonketotic hyperglycemia, especially when they have an inadequate diet, take medications that interfere with insulin metabolism (e.g., phenytoin [Dilantin], steroids), or take oral hypoglycemic agents [33]. Lactic acidosis may be present, in particular, with phenformin. These patients also tend to have focal or generalized seizures and transient or shifting hemiplegia as the level of coma deepens. The preservation of pupillary and oculocephalic responses helps to identify the clinical picture in such cases as being metabolic rather than structural.

The hyperosmolality occurring with hyperglycemia of any type causes a shift of water from the intracerebral to intravascular space with resulting brain shrinkage [34]. How this produces the neurologic changes observed is not known. More importantly, rapid correction of hyperosmolality by IV hydration and insulin results in cerebral water intoxication and signs of increased intracranial pressure. This is exemplified by the patient who begins to awaken from a hyperglycemic coma during IV therapy but later develops a headache and recurrent lethargy and seems to drift back into the previous state. Significant morbidity and mortality follow if these fluctuations are not observed and the IV treatment is modified appropriately [35]. Other details of the management of diabetic coma are addressed in Chapter 137.

Other Electrolyte Disturbances

Acute hyponatremia and hypernatremia cause fluid shifts and critical changes in serum osmolality, with the same effects on cerebral dysfunction as those described above. Mild to moderate acute hyponatremia (120 to 130 mEq per L) is evidenced by confusion or delirium with asterixis and multifocal myoclonus. If the serum sodium goes below 110 mEq per L, or drops at a rate more than 5 mEq/L/h to 120
mEq per L and below, seizures and coma are likely to follow. This course of events portends permanent neurologic damage even after careful therapy [36]. Common causes of hyponatremia are (a) the syndrome of inappropriate antidiuretic hormone secretion, with myriad etiologies; (b) excess volume expansion with hypotonic IV solutions; and (c) renal failure with a decreased glomerular filtration rate [37]. Other less common causes include psychogenic polydipsia, severe congestive heart failure, and Addison’s disease.

The neurologic signs of hyponatremia are nonspecific, and the general approach to evaluation of an encephalopathy often identifies the problem. Treatment is directed toward the underlying cause with fluid restriction in mild cases, unless total body sodium is depleted. In moderate cases (i.e., a serum sodium of 105 to 115 mEq per L), per os (PO) sodium supplementation may be needed as well. A serum sodium below 100 mEq per L is life-threatening. Correction of hyponatremia requires ICU monitoring and calculated sodium replacement (see Chapter 199). Excessively rapid correction of severe hyponatremia, especially in alcoholic or malnourished individuals, can be associated with another rare but serious neurologic complication known as central pontine myelinolysis (CPM) [38]. CPM starts with a flaccid quadriplegia and inability to chew, swallow, or talk, or “locked-in syndrome” developing over a period of days. Patients who recover from the underlying systemic disorder may be left with a spastic paraparesis and pseudobulbar speech; almost half may improve significantly over several months.

Hypernatremia is not seen very often outside the hospital setting except in children with severe diarrhea and inadequate PO fluid intake. Excess diuretic therapy, hyperosmolar tube feedings, and restricted access to PO fluids are reflected in a serum sodium of more than 155 mEq per L usually seen in institutionalized patients. Clinically, one sees progressive confusion and obtundation in subacute cases. With levels of sodium more than 170 mEq per L developing acutely, the brain may shrink, and subdural hematomas can occur as a result of stretching of the dural vessels. These patients may complain of headache, develop seizures, or simply drift into a stupor. Catastrophic complications such as venous sinus thrombosis and irreversible coma are seen with a serum sodium level of more than 180 mEq per L due to the marked hyperosmolality that accompanies it.

The cause of profound hypernatremia is often diabetes insipidus, which may be secondary to head trauma or other structural lesions of the hypothalamic stalk. Impaired thirst mechanisms or depressed consciousness interfere with the polydipsia that is pathognomonic of diabetes insipidus [39]. The treatment of symptomatic hypernatremia depends on its cause: dehydration alone or complicated by additional
sodium depletion due to hyperosmolar diuresis or excessive sweating. Fluid replacement is accomplished with 5% dextrose and water at a rate dependent on the total body water deficit—half of the water needed being administered IV in the first 12 to 24 hours and no faster (see Chapter 199). Saline solutions of half normal strength (0.45%) are used in most other cases. The exception is hyperosmolar diabetic coma, in which insulin and normal saline are both necessary to correct the severe serum hypertonicity.

Metabolic acidosis by itself produces only mild delirium or confusion [40] but may be accompanied by organ failure, direct CNS toxicity from drug metabolites, or volume depletion. The first sign of an encephalopathy caused by metabolic acidosis is hyperpnea followed by mental status changes and mild muscular rigidity. Ingestion of toxic doses of poisons such as methanol, ethylene glycol, and salicylates results in encephalopathy along with low serum bicarbonate levels (less than 15 mEq per L) [41]. Therapy must be directed toward vigorous correction of the metabolic acidosis while the specific cause is being elucidated.

Pancreatic Failure

Acute pancreatitis rarely leads to mental status changes during the initial bout. When recurrent or chronic, symptoms of encephalopathy may prominently wax and wane [42]. The clinical presentation is abdominal pain followed over 2 to 5 days by hallucinosis, delirium, focal or generalized seizures, and bilateral extensor Babinski responses. As the serum amylase continues to rise, the patient may lapse into a coma as a result of secondary hyperglycemia, hypocalcemia, and hypotension. The exact cause of the encephalopathy is unknown; the prognosis and treatment depend on the underlying cause and severity of the pancreatitis [43].

Endocrine Disorders

Adrenal disorders are an important consideration in acute encephalopathy, because hypo- and hyperadrenalism produce alterations in CNS function.

Addison’s disease or secondary adrenocortical deficiency occurs acutely in the setting of septicemia, surgery, and, most frequently, sudden withdrawal of chronically administered steroids. In the latter, one does not see the stigmata of chronic adrenocorticotropic hormone deficiency but rather hypotension, a mild hyponatremia, hypoglycemia, and hyperkalemia, together with a delirium or stupor that fluctuates erratically [44]. The electrolyte disturbances in most cases are not severe enough to explain the encephalopathy; other pathologic mechanisms such as cerebral hypoperfusion or water intoxication have been
suggested. Unlike many metabolic encephalopathies, adrenocortical insufficiency is associated with decreased muscle tone and deep tendon reflexes. Seizures and papilledema may appear when the patient has a profound adrenocorticotropic hormone deficiency and coma. The neurologic picture does not clear until cortisone replacement is given along with treatment of the electrolyte imbalances. These patients are also particularly sensitive to sedative medications and may lapse into coma with small doses of narcotics or barbiturates [45].

*Excess steroids* produce different forms of encephalopathy depending on whether the source is endogenous or exogenous. In Cushing’s disease, psychomotor depression and lethargy are the norm, whereas high doses of prednisone usually cause elation, delirium, or frank psychosis [46]. The latter is not uncommon in the ICU setting due to the administration of stress levels of steroids and multiple other CNS toxins. The behavioral changes are key to recognizing this problem because there are no specific metabolic markers [47]. Treatment consists of withdrawal of the steroids and sometimes temporary use of tranquilizers or lithium for the psychiatric features as well. Full neurologic recovery may lag behind the treatment by several days to weeks.

*Hypothyroidism* is now a rare cause of encephalopathy and coma. It may be confused initially with other causes of hypotension, hypoventilation, and hyponatremia, such as septic shock, brainstem infarcts, or an overdose of sedatives. The diagnosis should be considered in any patient with hypothermia, pretibial edema, pseudomyotonic stretch reflexes (e.g., delayed relaxation of the knee jerk), and coarse hair or facies. Muscle enzymes, serum cholesterol, and lipids may be elevated along with the thyroid-stimulating hormone (TSH) level [48]. Diagnostic confirmation is often delayed pending results of thyroid function tests, but replacement therapy should be initiated early with IV triiodothyronine or thyroxine. The constitutional symptoms may take several weeks to respond, but the neurologic picture clears promptly with proper treatment. Another form of hypothyroid-associated encephalopathy is seen in Hashimoto’s thyroiditis with a subacute subtle change in personality, memory deficits, and cerebellar ataxia accompanied by cerebellar atrophy on imaging studies. Confirmation of the diagnosis requires specific tests for antithyroglobulin and antithyroperoxidase antibodies along with an elevated TSH. Treatment with thyroid replacement therapy often results in recovery over a few months.

---

*Thyrotoxicosis* is more difficult to recognize because it can present in
an apathetic form, as a thyroid storm, or in a subacute form. Elderly patients are more likely to appear depressed or stuporous and without evidence of hypermetabolism [49]. The key to the diagnosis in such cases is evidence of recent weight loss and atrial fibrillation, often with congestive heart failure and a proximal myopathy. In a thyroid storm, the patient with indolent hyperthyroidism may be stressed by an infection or surgery and responds with marked signs of hypermetabolism: tachycardia, fever, profuse sweating, and pulmonary or congestive heart failure. Neurologically, the individual becomes acutely agitated and delirious and then progresses into a stupor [50]. The subacute picture that precedes this is one of mild irritability, nervousness, tremors, and hyperactivity, and is often misconstrued as an affective disorder rather than endocrine in origin. Ophthalmologic signs such as proptosis, chemosis, and periorbital edema are useful in identifying this form of thyrotoxicosis.

Therapy for thyrotoxic encephalopathy is aimed at ablation of the gland, but supportive care may require β-blockers, digoxin, diuretics, and sometimes dexamethasone and sedatives for the associated hypermetabolic state. Encephalopathy is also seen in disorders of the pituitary gland and parathyroid gland, although rarely as a primary process. Hypopituitarism may result from radiation or surgery to the area of the sella and can present as a chronic encephalopathy with features of thyroid or adrenal insufficiency, or both. An acute coma due to infarction or hemorrhage of the pituitary gland, known as pituitary apoplexy, can be seen in acromegalis with large adenomas or in patients with postpartum hemorrhage and hypotension (Sheehan’s syndrome) [51]. Subarachnoid blood and ocular abnormalities plus signs of increased intracranial pressure help to identify the pituitary lesion in such cases. Encephalopathy from hyperpituitarism reflects the specific neurohumoral substance that is being released in excess and does not represent a unique syndrome.

Hyperparathyroidism may be manifest neurologically with asthenia or a vague change in personality. The patient is mildly depressed, lacks energy, and fatigues easily. A serum calcium more than 12 mg per dL and elevated parathormone levels are important diagnostic findings. Occasionally, psychiatric symptoms predominate, starting with delirium and psychosis, or obtundation and coma when the serum calcium exceeds 15 mg per dL. Hypercalcemia caused by metastatic bone lesions, paraneoplastic parathormone-like substances, sarcoidosis, primary bone diseases, and renal failure are associated with a subacute or chronic encephalopathy similar to hyperparathyroidism. Treatment in these cases must be directed toward the underlying disease rather than addressing the hypercalcemia alone. Primary hyperparathyroidism is effectively managed by ablation of the overactive gland. This is not always possible,
because the glands often are ectopic and may escape discovery on selective angiography or exploratory surgery.

Hypocalcemia due to hypoparathyroidism produces an encephalopathy that parallels the depression of serum calcium levels. At less than 4.0 mEq per L calcium, a blunted effect and seizures are common and may be confused with a dementing process or epilepsy. The motor signs of hypocalcemia, that is, tetany or neuromuscular irritability, should make one suspicious of a metabolic disturbance [39]. Another diagnostic dilemma is the occasional presentation of hypocalcemia with papilledema and headache. The opening pressure on lumbar puncture is elevated to the same degree as in pseudotumor cerebri, but a head CT is likely to show basal ganglia calcifications [48]. Furthermore, the presence of cataracts and mental dullness in a previously normal individual should lead one to check the serum calcium and parathormone levels.

The mechanism by which hypocalcemia and hypoparathyroidism produce these varied neurologic symptoms is not known. Replacement of serum calcium by dietary means is usually inadequate to correct the CNS disorder. Supplementation with vitamin D and calcitriol enhances the absorption and utilization of oral calcium.

Other Causes of Encephalopathy

The list of causes of diffuse or metabolic encephalopathies is so lengthy that the problem of diagnosis must be resolved by a process of elimination. Drugs and toxins lead all other possible causes, with a frequency of approximately 50% (see Chapters 97 through 126). Hepatic, renal, or pulmonary failure is causative in another 12% and endocrine or electrolyte disturbances in approximately 8%. Other less common etiologies include thiamine deficiency (Wernicke’s encephalopathy), cardiac bypass surgery, subacute bacterial endocarditis, and hyperthermia. All of these disorders produce microembolic or microhemorrhagic/petechial lesions in specific areas of the brain.

Wernicke’s encephalopathy develops acutely in the clinical setting of an alcoholic or a malnourished individual, especially when IV glucose solutions without vitamin supplementation are given. Because thiamine is a cofactor in the utilization of cerebral glucose, it is depleted by the IV infusion [52,53]; confusion, obtundation, and loss of short-term memory rapidly ensue. The hallmark of this entity is a striking impairment of ocular movements, causing an external ophthalmoplegia, nystagmus, and diminished oculocephalic responses. Prompt IV and PO administration of 100 mg thiamine restores ocular function completely. The cerebral symptoms resolve slowly with the addition of 100 mg PO thiamine daily for 3 days or more. If untreated, the patient may lapse into a coma due to autonomic failure with accompanying shock and hypothermia and often
death. Repeated or untreated episodes of Wernicke’s disease may result in a chronic Korsakoff’s psychosis with profound memory impairment [49].

More recently, recognition of autoantibodies to potassium channels (VGKC-Ab) and N-methyl-D-aspartate receptors presenting with a subacute limbic-type encephalopathy has led to exciting research into the role of channel blockade in reversible mental status changes. In many cases, there is no evidence of an occult cancer (e.g., testicular or ovarian in young people) and the prognosis with immunoglobulin or steroid therapy is good [54].

_Hyperthermia_ due to heat stroke also has a characteristic clinical setting—young individuals experiencing excessive sweating caused by overactivity and elderly people receiving anticholinergics who are exposed to a hot environment [51]. In both cases, neurologic changes occur when the core body temperature reaches 42°C (107.6°F). The patient may become agitated and confused with intermittent generalized seizures or may immediately lapse into a coma as if due to a stroke. The presence of tachycardia, hot and dry skin, and diffuse hypertonus occurring in the appropriate circumstances identifies the likely etiology. Normal pupillary size and reflexes (except with anticholinergics) and oculocephalic responses, and the absence of focal motor signs also point to a nonstructural lesion. However, if the core body temperature is not lowered early in the course, the patient may be left with sequelae similar to those seen in hypoxic–ischemic encephalopathy. Other causes of temperature more than 42°C are rare and are not discussed here [55].

Up to 20% of patients with bacterial or marantic endocarditis can present with a subacute encephalopathy manifested by confusion and hyperpnea with or without fever [56]. It should be suspected in any patient with gram-negative sepsis [56]; ovarian cancer; malignant melanoma; adenocarcinoma of the lung, breast, prostate, or pancreas; and an immunocompromised state. Definitive diagnosis rests on the blood culture results and an echocardiogram showing vegetations. Treatment is directed toward reducing or removing the cardiac source.
CONCLUSIONS

Metabolic encephalopathy is one of the most frequently seen neurologic disorders in the ICU. It is also one of the most diverse in its clinical presentations and requires a systematic approach to define the etiology and to institute effective treatment. The features that distinguish most metabolic encephalopathies from structural lesions are (a) a nonfocal neurologic examination, (b) increased motor activity, (c) intact ocular and pupillary reflexes, and (d) laboratory abnormalities that support the clinical picture. Additional tests such as an EEG, head CT, or toxicology screen are useful in ruling out other possible causes.

One should keep in mind that many patients in the ICU have an underlying chronic encephalopathy due to long-standing illness. Therefore, they are more susceptible to minor metabolic perturbations induced by small doses of drugs, slight shifts of fluid balance, or worsening organ failure. Early recognition and correction of such factors improve the patient’s prognosis for a full neurologic recovery. Toward this end, it is prudent to consult the neurologist before the complications of multiple treatments and further changes confound the clinical course.

10. Foster JW, Hart RG: Hypoglycemic hemiplegia: two cases and a

Cognitive dysfunction following major surgery is one of the common reasons neurologists are asked to see postoperative patients in the intensive care unit (ICU): patients whose memory and intellectual abilities seem impaired when they otherwise appear to have recovered physically from the immediate effects of surgery. Cognitive dysfunction is not the same as delirium or encephalopathy, nor is it the same as an altered state of consciousness. It is a major concern for the family, the patient, and the physician when a patient is found not to be intellectually the same on awakening following surgery as he or she was before. Most patients will return to their preoperative levels of cognitive functioning within 1 to 3 months of surgery [1,2], but a percentage of patients will have persistent changes for months and even years later, and the precise pathophysiologic mechanisms for this have yet to be elucidated.

There has been extensive research on cognitive changes following major cardiac and major noncardiac surgeries. It is, however, difficult to compare the studies in literature reviews and meta-analyses directly because of differences in the methods used, including patient sampling, specific tests used, testing intervals, definition of cognitive decline, variable consideration of comorbid factors, and lack of comparison groups [1,3]. Despite these differences, increased age and risk factors for cerebrovascular disease have been the most consistent factors associated with postoperative cognitive dysfunction [2,4].
MENTAL STATUS EXAMINATION IN THE INTENSIVE CARE UNIT

The primary objectives of a mental status evaluation in the ICU are to screen for the presence of postoperative cognitive decline, delirium, or neurologic events such as stroke or transient ischemic attack. Examiners analyze the nature and extent of the impairment, and change over time. Cognitive changes may be obvious when there are gross deficits in learning, memory, attention, or concentration. The decline can also be subtle, with problems in initiative or planning.

Many mental status screening tests are available [e.g., 5–10]. The Confusion Assessment Method for the ICU (CAM-ICU [10]) was designed and validated in the ICU, and can be used on intubated and nonverbal patients. A brief screening test may provide a general impression of the patient’s mental status, but the clinician must be able to assess areas of relative strength and weakness in greater depth. The following is offered as an outline for a mental status evaluation in the ICU [11–13].

Behavioral Observation and Patient Variables

Visual observation of the patient in the ICU is an extremely useful part of the mental status examination. Many details can be gathered from the moment the examiner enters the room, including the patient’s alertness, the use of sedating medications or mechanical ventilation and their level of mental acuity. Determining the patient’s level of arousal and attention is the essential first step in a mental status examination. Arousal may range from unresponsiveness to noxious stimuli, minimally responsive to voice or touch, normal alertness, hyper-alertness, or even manic states. Attention is the patient’s ability to maintain sustained focus on a task. Mental status examination depends greatly on arousal level and attention, and it is difficult to interpret higher cognitive functions when these are not adequate.

A patient who is easily distractible will perform poorly on most cognitive tests. Lack of motivation and effort during testing can have deleterious effects on test performance, and may lead to an overestimation of cognitive impairment. Abnormalities in mood and affect, and behavioral disturbances such as psychosis, disinhibition, hyperactivity, or impulsivity will also negatively impact the patient’s test performance. Test performance is compromised by postoperative pain, use of analgesic and sedating medications, limitations in strength and mobility, and possible sensory loss. Regardless, limitations of testing give the examiner useful information about the patient’s current status and
ability to interact with his or her surroundings.

Other patient factors that can influence test performance include demographic variables such as premorbid cognitive abilities, age, gender, education, cultural background; and medical and psychosocial history including psychiatric history, social history, and present life circumstances. A history from family members is extremely useful in defining these variables.

Attention

The patient’s level of attention can be assessed at the bedside using digit span, which also depends on immediate verbal recall. Repetition of digits both forward and backward should be evaluated. Both tests consist of increasingly longer strings of random number sequences that are presented aloud to the patient. Seven digits forward (plus or minus two) is the average score obtained by adults. Digits backward normally does not differ from forward span by more than two digits. If preferred, spelling WORLD forward and then backward or alphabetizing the word EARTH can be alternatives to using digit span [7,14].

Perseverance or the ability to sustain behavioral output can be measured at the bedside by mental tracking tests. Reciting the alphabet or days of the week forward requires minimal perseverance. Examples of more discriminating attention tests include serial subtraction of 7s from 100 to 65 [7] or reciting the months of the year backward.

Resistance to interference and response inhibition are examples of executive functioning and can easily be observed during testing informally. Patients who struggle with task switching, perseverate on previous tasks, and who answer impulsively or intrusively show poor executive functioning. This can be tested formally with motor sequencing tasks. Examples include the “go-no-go” test (when the examiner taps once, the patient taps twice, but when the examiner taps twice the patient does not tap [15]); or the patient listens to a list of letters and taps his or her hand when they hear the identified letter [8]. Vigilance can also be tested by writing alternating sequences (e.g., copying a sequence of script such as m n m n m n [16]). Patients with impaired attention may perseverate on one element of the task rather than alternating between the sequences. A useful test of attention is having the patient do a verbal alpha-numeric sequence—alternating letters and numbers through the alphabet (A-1, B-2, C-3...to Z-26).
Speech output should be assessed for fluency (rate and effort of speech), articulation (normal or dysarthric), phrase length, prosody (melody, rhythm, inflection), content (semantics and syntax), and paraphasias (substitutions of rhyming alteration of words). Output can be observed in verbal responses to open-ended questions or by having the patient verbally describe a complex visual scene, such as a photograph (“propositional speech”) or the Cookie Theft Picture [17]. The patient can be asked to tell someone who has never seen one, “what is a dog?; or “what is a box?” Disorders of repetition can be elicited by having the patient repeat phrases that vary in grammatical complexity (e.g., “Today is a sunny day” vs. “no ifs, ands, or buts”).

Auditory comprehension can be assessed at the bedside in a number of ways. Examples include pointing to named objects, such as body-part identification (e.g., “Point to your left thumb,” “show me two fingers on your right hand,” “point to the ceiling after pointing to the floor,” “point your way out of this room”) and following multistage oral commands. Speech comprehension can also be assessed by asking “yes/no” questions such as “Do cows fly?”

Common objects (e.g., watch, pen, eyeglasses) can be used to test naming to confrontation. Component parts (e.g., lens, frame) may detect more subtle naming deficits. Oral reading can be done at bedside by having the patient read a brief passage from a newspaper, and then asked “yes-no” questions about its content.

Asking the patient to write a sentence of their own or copy from dictation are excellent screening tests for aphasic writing deficits. Comprehension can also be assessed by having the patient follow written directions (e.g., “Point to the ceiling” or “close your eyes” [7]). Word-list generation by specific category (e.g., animals, items found in supermarket or hardware store) and by specific initial letter are sensitive to both language and attention disorders.

**Memory Functions**

Memory functions include immediate memory span, learning capacity and retention, and retrieval of previously learned information (recent and remote). Immediate memory span is commonly assessed with a digit span forward test (described previously). Learning capacity can be investigated in a number of ways. For example, three or four unrelated words are presented and the patient is instructed to remember them. After 5 minutes of other testing, the patient is asked to recall the words. Nonverbal learning can be assessed in a similar fashion using line drawings of simple geometric figures or by pointing to three or four objects in the room and asking the patient to recall them a few minutes later.
Remote memory can be tested by asking questions about political figures (e.g., naming the three previous Presidents), dates or details of major world events, and personal history (e.g., name of high school attended).

**Visuospatial and Visuoconstructive Abilities**

Visuoconstructive ability is tested by having the patient copy simple figures (e.g., cube, daisy, interlocking pentagons). Spatial planning can be assessed with clock drawing. The patient is asked to draw the face of a clock and to fill in all the numbers. Left-sided visual inattention or hemispatial neglect is suggested if the patient places all the numerals on one side of the clock, or omits all numerals normally on one side. Capacity to process number/time relationships can be tested by having the patient “Set the time to 10 minutes past 11 o’clock.”

**Executive Functions and Other Cognitive Abilities**

Executive functioning status is gathered throughout the examination as described above, monitoring for ability to switch tasks and inhibit responses when needed. Abstract thought can be assessed by asking how word pairs are alike. An example of an easy similarity test pair is “broccoli–cauliflower”; a more difficult pair is “fish–dandelion.” Mental arithmetic problems (e.g., “How many quarters are in $1.50?”) test reasoning ability as well as immediate memory and concentration. Insight and judgment can be approximated when discussing the patient’s recent medical care, their understanding of their status; and their ability to manipulate data, make and maintain a decision regarding the next steps. Unfortunately, there are no reliable tests of judgment. Patients may be able to describe an appropriate response to how they would handle a scenario (e.g., a small emergency), but may not behave so in a real situation.
MENTAL STATUS DYSFUNCTION IN THE INTENSIVE CARE UNIT

Acute Confusional State (Delirium)

Delirium is a very common cause of mental dysfunction in postoperative patients in the ICU. The hallmark features of delirium are inattentiveness, confusion, and psychomotor agitation, as well as sleep–wake alterations, and in many patients hyper-alertness, with hallucinations or visual misinterpretation of common objects. Hypoactive delirium with alterations in arousal is often under-recognized. Fever, sepsis, metabolic and endocrine disturbances, as well as medication use or withdrawal are among the causes of delirium; this is discussed in more detail in Chapters 145 and 157.

Focal Syndromes

Stroke is another adverse neurologic outcome from surgery—especially cardiac surgery [2] or endovascular procedures, such as angioplasty—and is usually recognized by the presence of focal or lateralizing deficits of sudden onset with motor weakness or sensory deficits (see Chapters 149 and 150). Focal cognitive deficits indicative of cortical dysfunction include aphasia, apraxia, and agnosia. These can be discovered by a careful and thorough mental status examination.

Postoperative Cognitive Decline/Dysfunction

As previously noted, changes in memory and concentration are often seen in the ICU in the initial postoperative period. These changes can, however, persist beyond the immediate postoperative period when the effects of anesthesia and analgesia directly affecting cognitive functions have clearly worn off. Most mental status changes improve, but in some cases may continue following discharge, even weeks, months, and years later with associated impaired quality of life and increased mortality [4,18].

Elderly patients undergoing major cardiac (e.g., coronary artery bypass grafting, thoracic vascular surgery) and major noncardiac (e.g., orthopedic, abdominal) surgery are at the greatest risk for postoperative cognitive decline. Other individual features that increase the risk of mental status dysfunction include previous cerebrovascular disease, previous and undetected cognitive impairment or dementia, and
cardiovascular risk factors such as hypertension, diabetes, and peripheral vascular disease [2,19–23].

Intraoperative risk factors include surgical technique (e.g., duration of cardiopulmonary bypass, duration of aortic cross-clamping), hypotension, manipulation of diseased aorta, and the effects of general anesthesia and hypothermia. To assess these factors requires close scrutiny of the operative record, and of the anesthesia chart. Atherothromboembolic phenomena (microemboli) and hypoxia with watershed area injury secondary to hypoperfusion are possible causative mechanisms of postoperative cognitive dysfunction due to intraoperative events during surgery [2].

A number of postoperative factors can also affect cognitive status in the ICU, including the use of analgesics, degree of physical discomfort, and depression [3,24]. These factors may produce short-term but self-limited cognitive change. Nevertheless, they should be taken into account when assessing the mental status of a patient in the ICU.
SUMMARY

Testing for mental status dysfunction of a patient in the ICU can be a complex and difficult task. Interpretation of test results can be confounded by premorbid patient characteristics (e.g., presence of a dementing illness presurgically) and the patient’s current status (e.g., drowsiness in the context of high-dose analgesics, sedatives, and other medications). Mental status testing should not be attempted when arousal is abnormal or if the patient is too ill. The approach to testing should be flexible and targeted to the individual patient’s complaints and level of functioning. Postoperative cognitive changes can range from obvious deficits in concentration and memory to subtle deficits in executive functions. Evidence of abnormality during a screening evaluation warrants a thorough neurologic evaluation.

15. Drewe EA: Go no-go learning after frontal lobe lesions in humans.

Anoxic brain injury results from inadequate oxygen supply to the brain. The clinical picture ranges from mild confusion to deep coma with loss of brainstem responses. Anoxic damage can be caused by circulatory collapse; respiratory failure; or inadequate hemoglobin or its ability to bind and release oxygen. Prognosis and management of the anoxic patient depend in part on which of these mechanisms has caused the injury.

**PATHOGENESIS**

The brain is unique in that it uses almost exclusively aerobic metabolism of glucose. The continuous availability of oxygen is secured by the cerebral vasculature’s autoregulatory mechanisms [1], which control the rate of blood flow over a wide range of blood pressures. If blood pressure drops too low for autoregulatory mechanisms to operate, oxygen extraction from the blood increases. Failure of this compensatory mechanism results in a changeover from aerobic to anaerobic metabolism.

In cardiac arrest (CA), depletion of brain oxygen reserves occurs within 10 seconds, thereby eliminating the major source of neuronal energy from ATP (adenosine triphosphate) and phosphokinase. Excessive glutamate release and reduced reuptake lead to activation of the NMDA (N-methyl-D-aspartate) receptors and consequent ischemic cascade. The resulting intracellular (cytotoxic) edema leads to increased intracranial pressure. The changeover to anaerobic metabolism results in neuronal catabolism. In cardiovascular collapse, loss of venous outflow leads to the
accumulation of lactic acid and pyruvate, the end products of anaerobic metabolism. Buildup of these catabolites potentiates neuronal damage.
DIAGNOSIS

The first question to address when evaluating a comatose or obtunded patient with a possible hypoxic insult is whether the impaired consciousness is the result of a metabolic insult or a structural brain lesion. Coma caused by a mass lesion is usually associated with focal neurologic signs. Computed axial tomography (CT) or magnetic resonance imaging (MRI) scans usually reveal focal lesions in this setting. Metabolic causes, including anoxic encephalopathy, should be suspected when patients with impaired consciousness present with a nonfocal examination.

The diagnosis is often suggested by the clinical setting (e.g., CA in patients with arrhythmias or myocardial infarctions, or severe episodes of intraoperative hypotension). Arterial blood gas determination, if obtained during the causal event, can confirm the diagnosis. Acute decrease in the partial pressure of oxygen to less than 40 mm Hg causes confusion, and to less than 30 mm Hg results in coma [2]. Associated abnormalities that potentiate anoxic damage include anemia, acidosis, hypercapnia, hyperthermia, and hypotension.

The internist or neurologist is often consulted to evaluate the patient who has impaired consciousness after well-documented cerebral hypoperfusion event that has occurred during surgical operations requiring the use of extracorporeal circulation. The neurological examination is usually nonfocal. Because surgical patients with such a history often have preexisting illnesses (vascular disease, borderline renal function, hepatic impairment, and diabetes), it is the obligation of the intensive care physician to determine whether the new deficits are caused by anoxic encephalopathy, or by other treatable conditions secondary to metabolic, infectious, or iatrogenic factors such as sedating medications. Intracerebral hemorrhage and subdural hematomas should also be sought, because they can occur spontaneously in the perioperative period, especially in anticoagulated patients.
CLINICAL COURSE AND PROGNOSIS

The clinical outcomes for patients with anoxic injuries depend on the degree and duration of oxygen deprivation to the brain as well as the maintenance of blood flow. With complete cessation of blood flow to the brain, consciousness is lost after several seconds. If anoxia is moderately prolonged, the patient awakens but may have residual deficits, such as cognitive impairment, or later sequelae, including extrapyramidal movement disorders or seizures, which may not develop for days to weeks.

A delayed postanoxic syndrome may occur rarely in patients with anoxic insults after the initial coma. Three to 30 days following the initial anoxic insult, after the patient has regained consciousness and cognitive function, there is a secondary decline characterized by irritability, confusion, lethargy, clumsiness, and increased muscle tone; patients may become comatose again and die. This uncommon condition occurs most often in cases of carbon monoxide poisoning. Pathologically, widespread demyelination is seen without gray matter changes. The cause is unknown, but it may be caused by alteration of enzymatic processes; edema; or damage to small blood vessels [2,3].

The overall prognosis for a meaningful recovery in patients with nontraumatic coma is guarded; the longer patients are in coma, the worse the outcome [4–6]. Maximal improvement usually occurs within the first 30 days. Non-anoxic metabolic coma carries the best prognosis, whereas anoxic coma has a better prognosis than coma resulting from structural lesions. A good outcome is seen in 50% of patients who awaken within 24 hours. Although infrequent seizures or myoclonus do not affect prognosis, myoclonic or nonconvulsive status epilepticus is a grave prognostic sign and is associated with poor recovery [4,7].

If consciousness is maintained during a hypoxic event, there is rarely permanent brain damage. Irreversible damage is rarely seen in healthy individuals if the duration of anoxia is less than 4 minutes, although it may occur for individuals with preexisting cerebrovascular disease in shorter periods.

In cases of nontraumatic coma, the most valuable prognostic information is obtained from the physical examination. Favorable prognostic indicators include the following:

1. Recovery of multiple brainstem responses within 48 hours (pupillary, oculocephalic, and corneal) [4].
2. Return of purposeful responses to painful stimuli by 24 hours.
3. Primary pulmonary event leading to coma.
4. Hypothermia at the time of the anoxic event may be protective.
5. Younger age [8].

Poor prognostic indicators in persistent coma include the following:

1. Absence of pupillary and corneal responses, and withdrawal response to pain in 24 hours [9].
2. The loss of vestibulo-ocular responses at 12 hours; presence of decerebrate or decorticate posturing at 24 hours; and absent motor response to pain by the third day [5,8,10].
3. Electroencephalogram (EEG) within 24 hours after CA showing unfavorable patterns such as isoelectric, low-voltage, and burst suppression with identical bursts [11].
4. Bilateral absences of the N20 of the somatosensory evoked potentials (SSEPs) of at least 24 hours’ duration [12].
5. Noncontrast CT scan shows lower gray–white matter ratio in comatose patients after CA [13].
6. Extensive abnormalities on diffusion-weighted imaging [14,15].
7. Myoclonus or status epilepticus the first day.

SSEPs are not abolished in reversible coma owing to metabolic or toxic causes, sedative or anesthetic administration, nor even in barbiturate coma, which makes its absence potentially useful in the diagnosis of brain death [16].

A recent Academy of Neurology Practice Parameter evidence-based review for predicting the outcome in survivors of cardiopulmonary resuscitation (CPR) suggests the following as poor prognosticators of outcome: Absence of pupillary light reflex, corneal reflexes, and motor response to pain; occurrence of myoclonus or status epilepticus. Serum neuron-specific enolase (NSE), and SSEP studies can assist in accurately predicting poor outcome in comatose patients after CPR for CA [17].

When prognosticating by the clinical criteria alone, one must be careful that no sedative, anesthetic, or anticonvulsant is being used, because these agents can suppress brainstem reflexes.

Generalized cerebral anoxia due to respiratory insufficiency, with maintained circulation, carries a better prognosis. A low partial pressure
of oxygen does not necessarily convey a bad prognosis in cases of isolated hypoxia, if circulation is carefully maintained [18,19]. Conversely, the presence of metabolic abnormalities, such as lactic acidosis, worsens prognosis.

In cases of out-of-hospital CA (OHCA), survival depends on the total time required to establish effective cerebral blood flow. The arrest time (AT) and the CPR time to effective cardiac function represent a continuum from absence of cerebral blood flow to effective circulation, and together represent the total duration of ineffective cerebral blood flow. Short AT is compatible with good outcomes even after longer periods of CPR, whereas increasing lengths of AT reduce the time window for successful CPR. If AT is less than 6 minutes, prognosis for recovery is related to CPR time; over half of patients on whom CPR is successful within 30 minutes make a good neurologic recovery. When CPR time is longer, prognosis for neurologic recovery drops significantly. If AT exceeds 6 minutes, and CPR time 5 minutes or less 50% recovered neurologic function. If CPR time was between 6 and 15 minutes 19% recovered neurologic function, and no patients recovered good neurologic function if CPR time was over 15 minutes [20]. The OHCA outcome differed by time to first CPR and first documented rhythm; shortening of time to first CPR is crucial for improving the OHCA outcome [21].

Unsuccessful CPR before arrival at the emergency room predicts a poor prognosis [22]. Emergency crew–witnessed arrests; consciousness level on admission; and requirement for ventilation are independently useful to predict in-hospital outcome and mortality [23].

Magnetic resonance spectroscopy demonstrating elevated lactate and reduced N-acetyl aspartate peaks is associated with a poor prognosis [24,25].

Cerebrospinal fluid (CSF) lactate levels, NSE, and brain-type creatine kinase isoenzyme levels, may have predictive value 24 hours after CA [26,27]. Patients with either serum NSE more than 33 μg per L at 24 hours, or CSF brain-type creatine kinase isoenzyme more than 50 U per L at 48 to 72 hours, had a poor outcome [12,28]. S-100 protein, an astroglial marker, is elevated in anoxic arrest. Values more than 0.2 mmol/L on Day 2 are associated with 100% mortality, whereas lower values are associated with a nearly 90% survival.

After OHCA, the overall probability of awakening is roughly 50% [29]. Much of this depends on the duration of the coma. The longer a patient survived without awakening, the smaller the probability of awakening without deficits [30,31]. In cases of OHCA, patients who are comatose on admission, but who awake to follow commands within 2 days, have an 80% probability of good neurologic function on discharge or later [29].
TREATMENT

Treatment approaches for CA and perioperative hypoxic encephalopathy are similar. Optimal therapy is directed at preventing the recurrence of hypoxia. To ensure that the oxygen-carrying capacity of the blood is restored, excess oxygen administration is suggested for several hours after anoxic events. Blood pressure is maintained at normotensive or mildly elevated levels. Mean arterial pressure should be 90 to 110 mm Hg in patients who are usually normotensive. The partial pressure of oxygen should be more than 100 mm Hg. The partial pressure of carbon dioxide is kept at the patient’s baseline (usually 40 mm Hg), unless there are active signs of cerebral herniation; if herniation is suspected, the patient should be hyperventilated. Mild hypovolemia and elevation of the head of the bed to 30 degrees reduce intracranial pressure. Vital signs, hematocrit, electrolytes, blood sugar, and serum osmolality should be maintained in the normal range. In all cases, a head CT or MRI scan and complete metabolic studies should be obtained to exclude structural and other functional causes. When any uncertainties exist, a neurologist should be consulted.

Seizures occur in 25% of patients in anoxic coma [4]. They are treated with loading and then maintenance doses of fosphenytoin (loading dose, 15 to 20 mg phenytoin equivalents per kg, rate not to exceed 100 mg phenytoin equivalents per minute; maintenance dose, 5 mg phenytoin equivalents per kg per day). Alternatively, intravenous phenytoin can be used (loading dose, 18 to 20 mg per kg; rate, 50 mg per minute; maintenance dose, 5 mg per kg). Other newer intravenous medications have the advantage of less drug interaction but no proven efficacy over the known medications. Their indiscriminate use can lead to escalation in health care cost without known non-inferiority or superiority. Patients with cardiac conduction abnormalities need to be carefully monitored while being loaded with fosphenytoin or phenytoin. Phenobarbital is usually avoided because of its sedative effects. If necessary, loading doses in adults are up to 500 mg intravenously, and maintenance doses are 2 to 4 mg/kg/d [32]. Because status epilepticus or frequent untreated seizures can further damage the brain, an EEG should be obtained if there is any question of subclinical epileptiform activity [9]. Some postanoxic patients develop delayed intention myoclonus. This can be distinguished from seizure activity because the latter is accompanied by an epileptiform discharge on the EEG, whereas myoclonus is not.

Steroids, mannitol, and glycerol are ineffective and result in elevated serum blood glucose, which increase production of lactic acid, possibly potentiating preexisting damage.
There is strong evidence that mild or moderate hypothermia may improve outcome after CA [33,34]. The 2010 American Heart Association (AHA) guidelines recommend cooling between 32 and 34 degrees in comatose adult patients with Return of Spontaneous Circulation (ROSC) after out-of-hospital ventricular fibrillation (VF) CA, for 12 to 24 hours [35]. Also induced hypothermia (IH) may be considered after in-hospital CA with any initial rhythm; or after OHCA with an initial rhythm of pulseless electrical activity or asystole [35]. A recent international trial of unconscious survivors in OHCA patients did not show a difference in neurological outcome following targeted body temperature of 33°C compared with a targeted body temperature of 36°C [36]. The authors raised the question of whether the observed benefit of hypothermia following CA is caused by prevention of fever, or a specific result of brain protection. This study does not alter the AHA guidelines to lower the temperature of patients following CA.

Summary of selected large randomized controlled trials (RCT) on the outcomes after IH on surviving patients with witnessed CA is outlined in Table 148.1.

Select RCT included.
CA, cardiac arrest; IH, induced hypothermia; OHCA, out-of-hospital cardiac arrest; ROSC, return of spontaneous circulation; VF, ventricular fibrillation.

Contraindications for therapeutic hypothermia (TH) include [37]:

1. Patients demonstrating rapid and complete neurological recovery.
2. Patients with Do-not-Resuscitate (DNR) orders.
3. Patients with active bleeding or those at high risk of bleeding.
SUMMARY

The effects of oxygen deprivation depend on many factors; the degree and duration of hypoxia are the most important. In cases of CA, brain damage is proportional to the amount of time without perfusion. The patient’s age, underlying medical conditions, infection, and other metabolic imbalances also play a role in the body’s ability to withstand oxygen deprivation.

Treatment strategies for the acute phase focus on supportive care. Elevation of the head of the bed; maintaining a relatively hypovolemic state; and avoidance of hypotension may be of benefit. A vigorous search should be made for concurrent metabolic abnormalities. Administration of steroids, osmotic agents, neuroprotective agents, and prophylactic anticonvulsants is ineffective and may worsen the prognosis.

Prognosis is best determined by the early return of brainstem and cranial nerve function. Absence of brainstem functions 72 hours after the event is associated with poor outcome [17]. Other poor prognostic signs include BAER showing no cortical waves 8 hours after the circulatory arrest; absence of cortical SSEP; and a CT scan demonstrating diffuse edema, loss of gray–white matter distinction, or watershed infarcts. The overall functional recovery rate is approximately 13%. If a patient has not regained consciousness by 6 hours after the onset of coma, the chance of survival for 1 year is 10%, and many of these survivors remain in a vegetative state.

IH improves outcome in CA survivors. Numerous studies have shown that TH can be applied safely with minimal side effects. More studies will be required to determine the optimal duration of TH, and identification of patients who might benefit from deeper or more prolonged hypothermia [38]. It might be possible that even less severely injured patients might benefit more from TH, aiding in better functional recovery—a possibility that can be explored in future studies.
REFERENCES

Cerebrovascular diseases encompass ischemic stroke from thrombosis or embolism, and hemorrhagic stroke including intracerebral hemorrhage (ICH) and subarachnoid hemorrhage. Many patients require management in the intensive care unit (ICU) owing to the severity of disease or for monitoring after acute thrombolytic therapy. This chapter reviews the basic concepts of pathogenesis, diagnosis, evaluation, and management for patients with ischemic cerebrovascular disease (ICVD) and ICH. Subarachnoid hemorrhage is discussed in Chapter 150.

ISCHEMIC CEREBROVASCULAR DISEASE

ICVD includes transient ischemic attack (TIA) and ischemic stroke and comprises 87% of all strokes; it is the most common neurologic problem that leads to acute hospitalization [1]. To facilitate accurate diagnosis and appropriate therapy, ICVD can be categorized along three axes: acuity, anatomic territory, and underlying mechanism.

Acuity

Stroke is a paroxysmal disorder, most frequently occurring suddenly and without warning. However, in the thrombolytic era, accompanying an increased understanding of the neuronal and vascular pathophysiology of ICVD, it has become increasingly important to conceptualize a stroke that “is happening” rather than one that “has happened.” This distinction reflects the circumstances when an opportunity to intervene to attenuate, prevent recurrence, or reverse the deficits related to ICVD exists and includes both TIAs and hyperacute stroke.

TIAs are brief episodes of neurologic dysfunction resulting from
cerebral ischemia not resulting in cerebral infarction [2]. Classically, symptoms last for a few to 15 minutes but occasionally may persist for hours. Risk of recurrent TIA or stroke is highest in the ensuing few days [3]. By contrast, patients with transient symptoms and evidence of infarction by imaging are properly diagnosed with stroke. Both acute circumstances represent unstable cerebrovascular conditions for which prompt evaluation and treatment is required.

Acute stroke, or sometimes “hyperacute” stroke, refers to the first several hours after a stroke has occurred, when thrombolytic therapy may be indicated. (Table 149.1). Labeling presently suggests the use of rt’PA in applicable patients within 3 hours, but this has recently been expanded to within 4.5 hours and is supported by approbation from the American Heart Association [4]. Beyond this period, and extending typically for the next 1 to 3 days, is the acute period in which care directed at minimizing worsening or recurrence is paramount. The subacute period extends through two weeks after the event and is often characterized by attention to rehabilitative efforts. Beyond this point—the chronic period—rehabilitative efforts continue, and the focus on optimizing long-term secondary preventive therapy is critical.

INR, international normalized ratio; IV rt-PA, intravenous recombinant
tissue plasminogen activator; PT, prothrombin time; TT, thrombin time.

Anatomic Territory

Two broad clinical anatomic categories of ICVD syndromes are
recognized, based on division of the cerebrovascular supply into those
areas supplied by the carotid system (anterior circulation) and those
supplied by the vertebral-basilar system (posterior circulation).
Symptoms commonly encountered in carotid system disease include
aphasia; monoparesis or hemiparesis; monoparesthesias or
hemiparesthesias; binocular visual field disturbance (hemianopia); or monocular visual loss. Symptoms that may be seen in vertebral-basilar system disease include hemianopia; cortical blindness; diplopia; vertigo; dysarthria; ataxia; and limb paresis or paresthesias, frequently with ipsilateral involvement of cranial nerve functions, and contralateral body involvement. Loss of consciousness or isolated vertigo rarely occurs without other vertebral-basilar symptoms (less than 5%). Other isolated symptoms, such as diplopia, amnesia, dysarthria, and light-headedness, usually do not serve as a basis for the diagnosis of vertebral-basilar disease; however, association with other brainstem symptoms may support this diagnosis [5].

**Underlying Mechanism**

Acute ICVD can be categorized as being owing to *large vessel thrombosis; small vessel thrombosis, cardioembolism; other known etiology; or stroke of undetermined etiology*. Large vessel atherothrombotic occlusion is caused by atherosclerosis in the carotid or vertebral-basilar arteries, and is a common cause of acute ICVD. The pattern and severity of the neurologic deficit depend on the arterial territory; completeness of occlusion; and extent of collateral flow [5]. Small vessel occlusion occurs frequently owing to lipohyalinosis of the lenticulostriate arteries or basilar penetrators, and results in a small area of cerebral infarction called a *lacune* (Fig. 149.1). If a lacune occurs in the internal capsule, thalamus, or basis pontis, substantial neurologic deficits may occur even with a small lesion. The most common lacunar syndromes are pure motor hemiparesis, pure sensory loss, ataxic hemiparesis, and dysarthria-clumsy hand syndrome [6].
The typical presentation of a cardioembolic stroke is with maximal deficit at onset, although a small minority may have a stuttering clinical course. Diagnosis may be difficult if the patient has coexistent large arterial lesions; as many as one-third of patients with a cardiac embolic source have another potential explanation for their strokes [7]. The most common cardiac sources associated with cerebral embolic events are outlined in Table 149.2. Nonvalvular embolic source with atrial fibrillation is associated with an annual stroke risk between 2.2% and 15% according to associated risk factors [8]. Transmyocardial infarction, atrial fibrillation, and mechanical valves are associated with a high risk, whereas the risk is lower for patients with bioprosthetic valves. Patent right-to-left cardiac shunts have been recognized by contrast echocardiography with increasing frequency among younger stroke patients. In the absence of a hypercoagulable state or atrial septal
aneurysm, a patent foramen ovale (PFO) is not considered a significant risk factor for cardioembolic stroke, because up to 25% of the healthy population have a small PFO [9].

The aggregated category of “other known” etiology includes rarer causes distinct from the other categories. This includes traumatic or spontaneous extracranial or intracranial arterial dissection, an important cause of stroke in patients under age 50. Thrombophilias, whether congenital or acquired, are more likely to impact the venous system but may be an unusual cause of artery occlusion including ischemic stroke. Border-zone infarction is caused by globally diminished cerebral blood flow resulting from cardiac arrest or systemic hypotension, often associated with cerebral arterial stenosis, resulting in focal infarction and deficits occurring in well-described patterns in the endarterial distribution between major vessels [10] (Fig. 149.2). In the carotid circulation, border-zone infarcts occur between the distribution of the middle cerebral artery (MCA) and either the anterior or posterior cerebral arteries.
FIGURE 149.2 T1-weighted magnetic resonance imaging scan demonstrating a watershed infarction (arrow) in the border zone between the middle and posterior cerebral arteries.

Stroke of undetermined etiology, or cryptogenic, is assessed after full evaluation for other known causes has been unrevealing. This nosologic entity is associated with better outcome than stroke of other categories and requires the treating clinicians to do a comprehensive evaluation when the cause of the stroke is not apparent.

Differential Diagnosis

Symptoms suggestive of ICVD may mimic the symptoms of other neurologic entities. An important distinction is between ICH and ICVD. Symptoms considered classic for ICH such as early obtundation, coma, seizures, headache, and vomiting are known to be insufficiently reliable to make that diagnosis, because a similar presentation may be seen with ischemic stroke. Conditions other than cerebrovascular events can occasionally cause acute focal neurologic deficits and must be also be considered. Primary or metastatic brain tumors with hemorrhage into the tumor may resemble a stroke (Fig. 149.3). Subdural hematomas may
rarely present with acute focal neurologic deficits and must be considered in elderly patients, even without a history of head trauma. Patients with migraine headaches sometimes develop focal neurologic symptoms either before or during the early phase of the headache. Rarely, these deficits may occur in the absence of a headache (acephalgic migraine) or may persist (migrainous infarction). Patients with focal seizures may develop sensory, motor, and aphasic symptoms that can mimic ICVD, although they are usually stereotypical and transient. Occasionally, focal neurologic deficits may follow seizures and persist for 24 hours or longer (Todd’s paralysis). Diffusion-weighted magnetic resonance imaging (MRI), abnormal in acute stroke, is most often normal in patients with Todd’s paralysis. An important, uncommon, and reversible cause of acute focal neurologic deficits is hypoglycemia, which should always be assessed before any aggressive treatment is initiated for a presumed ischemic stroke. Similarly, in young patients or patients with a psychiatric history, objective neurologic signs, or corroborative radiologic evidence must be established to avoid treating a functional paralysis with relatively aggressive therapy. Finally, worsening of an old deficit should prompt a metabolic/infectious evaluation, because the damaged lesion may act as a locus minoris resistentiae, with focal clinical worsening of a chronic deficit.
FIGURE 149.3 Malignant glioma with associated edema on a computed tomography scan in a patient who abruptly developed a pure motor deficit. The arrow points to the lacunar infarct.

Laboratory and Radiologic Evaluation

A comprehensive workup to determine stroke subtype and severity, and to identify possible multiple risk factors is important to determine effective treatment options. Urgent imaging should remain the goal for all potential stroke patients presenting acutely, with or without demonstration of a worsening neurologic status. Imaging also helps in the differential diagnosis and is key in protocols for therapeutic intervention with recombinant tissue plasminogen activator (rt-PA). Both
CT and CT angiogram and MRI studies (brain MRI, MR angiogram) are reliable and sensitive means of differentiating between ICVD, hemorrhage, and other mass lesions as well as defining the vascular territory involved. CT Perfusion or MR Perfusion studies can help guide the intravenous or endovascular therapy for equivocal or uncertain cases. MRI is more sensitive than CT for the identification of brain tumors and MRI can identify infarction at an earlier stage (after several minutes of ischemia). MRI based diffusion-weighted imaging (DWI) has important bearing on acute stroke diagnosis and treatment [11]. Selected cases of suspected intracranial hemorrhage with equivocal or negative findings on CT, MRI may detect subarachnoid, subdural, and intraparenchymal hemorrhage [12].

An electrocardiogram should be obtained to assess possible underlying or concurrent cardiac rhythm or ischemic changes. Confusion may arise because T-wave, ST-segment, QRS complex changes, and rhythm disturbances may occur secondary to the cerebral ischemic event. Two-dimensional transthoracic, or transesophageal echocardiography, and telemetry/Holter monitoring should be done routinely because patients often have more than one potential underlying pathophysiology, and a cardiac structural or rhythm abnormality may change the treatment approach (Fig. 149.4). For patients with cryptogenic stroke, prolonged ambulatory telemetry, or loop monitoring, may identify additional patients with hitherto occult atrial fibrillation [13]. A transesophageal echocardiogram should especially be considered in younger patients, patients with an enlarged left atrium, and for cryptogenic stroke victims of all ages [14,15].

**FIGURE 149.4** Echocardiogram in a patient with cardioembolic stroke, demonstrating a large thrombus (arrow) attached to the left mitral valve.
A study of the cervical and cranial vascular status is important to identify the location of the lesion; confirm the thrombotic etiology of the symptoms; provide important information regarding the risk of recurrence or deterioration; and help to identify relevant findings in patients appropriate for endovascular catheter-based thrombolytic therapies. MR-based or CT-based angiography can be used. CT angiography allows a more rapid triage than MRI, because every minute wasted before thrombolysis is initiated results in a progressive reduction of salvageable tissue. If a coronary CT angiography (CTA) or magnetic resonance angiography (MRA) cannot be obtained to image the craniocervical vasculature, carotid artery ultrasound—a fast, reliable, and noninvasive technique—should be employed for suspected ischemic stroke of the carotid system as well as small vessel stroke, because of a high incidence of coexisting large vessel atherosclerotic stenosis. Furthermore, transcranial Doppler ultrasound (TCD) can provide additional information about the status of the intracranial vessels, both in the carotid and vertebral-basilar arterial territories [16,17].

Complete blood count, partial thromboplastin time (PTT), prothrombin time (PT), comprehensive blood chemistry, chest radiograph, erythrocyte sedimentation rate, syphilis serology, and urinalysis should be obtained on day 1. Of these, if thrombolytic therapy is being contemplated, the blood glucose, PTT, PT, and platelet count should be obtained immediately as point-of-care tests. Fasting lipid profile, homocysteine, and C-reactive protein can be obtained by day 2. Other blood studies, including anticardiolipin antibodies, hypercoagulable testing (protein S, protein C, antithrombin 3, factor V Leiden, and prothrombin-2 gene mutation), serum viscosity, serum protein electrophoresis, and fibrinogen, should be performed for younger patients and for patients with a history of cancer, recurrent deep vein thrombosis, or a family history suggestive of an autosomal-dominant pattern of stroke. A lumbar puncture should be performed only when meningitis is suspected, for suspected vasculitis of the nervous system, or when diagnosis of subarachnoid hemorrhage is a consideration, despite a negative result in a brain imaging study (non-contrast computerized tomography [NCCT] or MRI). Electroencephalography may be helpful when associated seizure activity is suspected.

**Treatment**

The treatment of ICVD can be divided into three major categories: prevention, supportive therapy, and acute interventions.
Stroke Prevention

Stroke prevention has improved, as risk factors have been identified and treatments developed [18]. Adherence to a diet rich in fruits and vegetables and a regimen including routine aerobic exercise are important for cerebrovascular health. The treatment of hypertension and smoking cessation are helpful for the prevention of stroke. Systolic blood pressure reduction by 5 to 10 mm Hg may reduce relative risk of ischemic stroke by 20% to 25%. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers may offer additional protection against first or recurrent ischemic stroke. Patients with hyperglycemia should be aggressively treated to maintain euglycemic control. Use of HMG CoA reductase inhibitors (statins) reduces the risk of ischemic stroke by 16% to 30% for patients with or without underlying ischemic heart disease, and possibly improves the outcome after ICVD. The American College of Chest Physicians and American Stroke Association guidelines recommend starting all inpatients with hyperlipidemia (low-density lipoprotein [LDL] greater than 100 mg per dL) on a statin. More recent trials of statins suggest that reducing LDL cholesterol to 70 mg per dL is safe and may have a plaque stabilization effect [19]. Patients with symptomatic carotid artery stenosis of greater than 70% benefit from carotid endarterectomy, provided the combined mortality and morbidity of the surgical procedure in the treating institution is less than 5.65% [20]. For nonsurgical TIA or stroke patients, antiplatelet therapy with aspirin; aspirin and extended-release dipyridamole (25/200 mg) twice daily; clopidogrel 75 mg once daily; or ticlopidine 250 mg twice daily is beneficial [21,22]. Atrial fibrillation with or without valvular heart disease is associated with a high risk of stroke. Anticoagulation using warfarin reduces the absolute recurrent stroke relative risk by 8% in patients with nonvalvular atrial fibrillation. The annual risk of symptomatic hemorrhage is 1%, which can be minimized by keeping the international normalized ratio (INR) between 2 and 3 [15]. Several newer anticoagulants have shown benefit in reducing the risk of cardioembolic stroke [23–26] (Fig. 149.3). They have the notable advantage over warfarin at not requiring routine blood monitoring or dietary restrictions. However, the experience with these drugs is comparatively modest regarding their safety in elderly patients and with nonvalvular atrial fibrillation. In addition, reversal agents are not yet available for all of these agents (Table 149.3).

## Supportive Therapy

Supportive therapy for ICVD patients should begin upon hospitalization.
Elevated blood pressure should not be treated in the first 24 hours of an ischemic stroke unless malignant hypertension (>220 mm Hg systolic, 120 mm Hg diastolic) is present or other end-organ failure becomes evident (e.g., congestive heart failure, renal failure, and hypertensive encephalopathy). The blood pressure typically autoregulates spontaneously with bed rest; if it remains substantially elevated, it should be carefully lowered daily up to 20% of the mean arterial pressure.
Subcutaneous heparin or low molecular weight heparin therapy should be considered for immobilized ICVD patients to reduce the risk of deep venous thrombosis. As far as possible, indwelling urinary catheters and unneeded IV lines should be avoided, because they can serve as portals of entry for infections. Elevated temperature should be treated with antipyretics. Aspiration pneumonia can be avoided by delaying oral feedings until safe swallowing is demonstrated. Early mobilization and rehabilitation should be attempted.
Acute Treatment

Standard therapies for ICVD patients are directed at reversing the neurologic deficit and preventing progression. The National Institute of Neurological Disorders and Stroke (NINDS) trial demonstrated that patients treated with rt-PA within 3 hours of stroke onset had a 13% absolute greater chance of being free of disability or being left with minor disability at 3 months. The benefit was greatest for those treated within the first 90 minutes of stroke onset compared to those treated between 90 and 180 minutes. There was a 5.8% greater incidence of ICH in treated patients, as compared to placebo (6.4% vs. 0.6%). However, overall mortality at 3 months was comparable in the rt-PA and placebo groups. Predictors of ICH include large hemispheric infarcts, National Institutes of Health Stroke Scale (NIHSS) score greater than 23, and the presence of associated severe hypertension [27]. Subsequently, based on prospective trial (ECASS III) results, it is possible to extend the time window of intravenous rt-PA up to 4.5 hours. The absolute benefits, although significant, were, as expected, less in this extended time window (absolute risk reduction [ARR] of 7%). Although the study excluded patients over age 80; those on anticoagulation (irrespective of the INR or PTT); and those with diabetes mellitus and stroke, the validity of these exclusions has not been substantiated, and individual management should be decided for individuals based on the physician’s judgment [28]. The total dose of IV t-PA for stroke is 0.9 mg per kg, given as a 60-minute IV infusion, with 10% of the total dose given as an initial bolus. After rt-PA infusion, patients need to be admitted to the ICU or to a dedicated stroke unit. Blood pressure and neurologic status need to be carefully assessed at specified frequent time periods. Systolic blood pressure above 185 mm or mean blood pressure over 130 mm are treated with intravenous labetalol/nicardipine or dose-titrated intravenous sodium nitroprusside. Neurologic worsening should prompt an urgent CT scan to look for possible hemorrhagic conversion of the infarct. Anticoagulants and antiplatelet agents are avoided in the first 24 hours. IV access and invasive procedures should be kept to a minimum in the first 24 hours after rt-PA administration.

Patients presenting within 4.5 hours or selected patients beyond 4.5 hours with large artery occlusion (basilar artery, internal carotid artery, and proximal MCA) may benefit from intra-arterial interventions. The results of several contemporary trials each showed clear benefit of the use of intra-arterial thrombectomy in selected patients beyond the standard
of intravenous tissue plasminogen activator (IV tPA) therapy alone. These trials were undertaken after the development of stent-retriever thrombectomy devices, favored over earlier device iterations in both efficacy and safety. Each of these trials was terminated early when interim analyses showed significant efficacy of the endovascular treatment arms (Table 149.4). Consistent with the expected target population, most treated patients had occlusion in the proximal MCA, had severe stroke scores (NIHSS 16 to 17), and were treated with endovascular therapy in addition to IV rt-PA. The majority of patients were treated within 6 hours of symptom onset and had relatively subtle findings of ischemia on head CT. Favorable functional outcome at 90 days were significantly more frequent for the treatment arms of the trials; symptomatic ICH was not significantly higher than in the control groups.

Comparative results are listed as combined treatment (IV rt-PA + IA stent retriever clot removal) vs. IV rt-PA alone.

Bold denotes significant difference within study in favor of combined IV and endovascular therapy (14% to 31%).

IA, intra-arterial; IV tPA, intravenous tissue plasminogen activator

Anticoagulation with heparin or low–molecular weight heparin has been used traditionally without any proof of efficacy. Likewise, there is no evidence that supports the use of IV heparin anticoagulation to improve stroke outcome in progressive stroke. Furthermore, the risk of recurrent
stroke is low (2% to 3%) in the first few weeks after an acute ischemic stroke (AIS) [29,30]. Cardioembolic stroke patients have a higher risk of recurrence (4.5% to 8.0%) within 2 weeks of the initial event, especially with associated intracardiac thrombi. Heparin therapy may reduce this risk and may be considered within 24 to 48 hours of the initial stroke [29]. Patients with large infarcts should not receive heparin, because they have a higher risk of bleeding into the area of infarction [19,29]. An alternative and safer approach is to begin warfarin, as soon as the patient can safely swallow, leading to adequate anticoagulation within 4 to 14 days of stroke onset [31].

Aspirin may reduce the risk of stroke recurrence after TIA or established stroke and is widely used for this indication [20]. Combined aspirin and extended-release dipyridamole therapy may be more effective than aspirin alone in reducing stroke recurrence [21]. In aspirin-allergic patients, clopidogrel or ticlopidine can be used. The incidence of serious side effects is greater with ticlopidine, which may cause neutopenia and thrombotic thrombocytopenic purpura. Because thrombotic thrombocytopenic purpura has been reported with both drugs, weekly complete blood count and liver function tests should be done in the first 4 to 6 weeks of initiating therapy [32].

Cerebral edema among ICVD patients is maximal between 48 and 72 hours after onset, but may extend up to 5 days after onset for infarcts in the brainstem and cerebellum. Corticosteroids are not effective for ICVD [33]. Osmotic diuretics, such as mannitol, are of potential value for cerebral edema with mass effect associated with ICVD; we consider using pulse doses (1 g per kg, then 0.5 g per kg every 6 hours) if massive edema begins to develop. Intracranial pressure (ICP) monitoring to guide therapy should also be considered. Controlled hyperventilation is perhaps the fastest and most effective temporizing measure to reduce cerebral edema, but its effects are transient, and regional cerebral ischemia may worsen owing to vasoconstriction. Patients with large ischemic infarctions in the MCA territory are at risk of massive cerebral edema and herniation (malignancy MCA syndrome). Timely decompressive hemicraniectomy reduces the risk of death by 50% (1 in 2 patients) and improves the outcome by 25% (1 in 4 patients). Interestingly enough, the outcomes of this trial were independent of the site of infarction or the presence or absence of aphasia [33].

Summary

Advances are being made in the treatment of ICVD. It is clear that
successful therapy requires early appropriate intervention, directed by the CT/CTA/±CTP protocol. In large vessel occlusion with a viable penumbra, IV, rt-PA should be initiated and rapid transfer of the patient to a site where intra-arterial intervention is available should be the goal. Physicians should not wait for IV rt-PA to finish, but should initiate a transfer for possible thrombectomy as soon as practical. For all other situations, start IV rt-PA and transfer patients to a neuro-ICU for completion and post rt-PA management. Treatment of TIA has undergone a dramatic change since we recognized that the risk of a full-blown ischemic stroke is 10.5% after a cursory ER visit, and that this risk can be reduced by 80% with acute inpatient management for 1 to 2 days, as demonstrated by the Oxfordshire study and the 2009 stroke guidelines on management of TIA [2]. The recognition that acute high-dose statins reduce the risk of stroke and improve outcomes irrespective of the LDL levels is an important addendum to our management strategy within the acute period after an ischemic stroke. In the future, it is probable that a combination of treatments directed at the multiple metabolic and perfusion abnormalities associated with ICVD will be required [34].

Decompressive hemicraniectomy with duraplasty is highly effective in reducing death or disability related to large MCA infarcts, with 50% absolute survival rate and 25% improved chances of a good outcome. Finally, stroke prevention is the most effective means of reducing the first or recurrent stroke. Aggressive use of statins for patients with either hyperlipidemia or elevated C-reactive protein reduces the risk of progression of atherosclerotic small and large vessel disease and may have a cardioprotective role (Table 149.5).

</tr>
</tbody>
</table>
• In malignant MCA syndrome, early DHC increases survival by 50% and improves outcome by 25% in malignant MCA syndrome.

• Stroke prevention strategies: BP <140/90 (ACEI/ARB preferred); lipid reduction of LDL <70 mg/dL with statins; aggressive DM control, HBA1c <7%; and low-dose aspirin are highly effective in reducing the risk of first or recurrent stroke.

• ICH
  • Early reduction of SBP to 140 improves survival.
  • Rapid reversal of anticoagulation to INR <1.4 may improve survival.
  • Intraventricular shunts may be helpful in improving survival in patients with ICH and IVH.
  • Surgical decompression in cerebellar hemorrhage >3 cm diameter or with brainstem compression and obstructive hydrocephalus improves neurologic outcome and survival.
  • Hematoma evacuation or decompressive hemicraniectomy after ICH are of unproven benefit.

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; DHC, decompressive hemicraniectomy; DM, diabetes mellitus; HBA1c, glycated haemoglobin; IA, intra-arterial; ICH, intracerebral hemorrhage; ICVD, ischemic cerebrovascular disease; INR, international normalized ratio; IVH, intraventricular hemorrhage; IV rt-PA, intravenous recombinant tissue plasminogen activator; LDL, low-density lipoprotein; MCA, middle cerebral artery; SBP, systolic blood pressure; TIA, transient ischemic attack.
INTRACEREBRAL HEMORRHAGE

Nontraumatic ICH occurs less frequently than ICVD, but carries a higher morbidity and often requires management in the ICU. The majority of these cases are caused by spontaneous (primary) ICH, defined as bleeding within the brain parenchyma without an underlying cause, such as neoplasm, vasculitis, bleeding disorder, prior embolic infarction, aneurysm, vascular malformation, or trauma. One-half of primary ICH cases result from longstanding hypertension. Owing to the aggressive control of hypertension, the incidence of ICH has decreased since the mid-1960s. Nonetheless, ICH accounts for 4% to 11% of all stroke cases in the USA and 16% to 26% of all stroke-related deaths [35].

Pathophysiology

Primary ICH is believed to be caused by extravasation of arterial blood from ruptured microaneurysms along the walls of small intracerebral arterioles. Microaneurysms known as Charcot–Bouchard or miliary aneurysms tend to form on vessels at the usual sites of ICH and develop at sites of vascular branching where mechanical stress is maximal. The aneurysm wall lacks normal vascular histology and is composed mainly of connective tissue layers, which represent a weak point in the arterial system. The formation of these aneurysms is favored by the processes of lipohyalinosis and fibrinoid necrosis, which weaken the walls of arterioles, and are accelerated by chronic hypertension. Although Charcot–Bouchard aneurysms also appear in the normotensive aging brain, their frequency is notably increased in hypertensive patients. They are commonly observed along the lenticulostriate arteries, thalamoperforate arteries, and paramedian branches of the basilar artery. Although this distribution corresponds to the common sites of ICH, it is impossible to prove that these aneurysms are always the cause of bleeding, and the concept of arteriolar microdissection has been raised as an alternative explanation [35].

In elderly patients, particularly those with a history of cognitive impairment or dementia, lobar ICH related to amyloid angiopathy is an important underlying mechanism [36]. Five to ten percent of cases of spontaneous ICH result from amyloid angiopathy, making it second to hypertension as an etiology for ICH [37]. Age-related deposition of β-
amyloid along the small arterials is thought to increase vessel wall fragility through decreased elasticity and render the artery susceptible to spontaneous rupture [38]. Diagnosis of this mechanism is often presumptive as proof of amyloid deposition via brain biopsy can be prohibitively invasive, particularly as therapy is supportive and an imaging signature showing multiple lobar areas of microhemorrhage is diagnostically supportive [39].

Continued extravasations of blood result in the formation of a hematoma with secondary accumulation of cerebral edema. The lesion may become massive enough to cause midline shift of cerebral structures followed by transtentorial herniation, which leads to secondary brainstem hemorrhages known as Duret hemorrhages. These linear lesions in the midbrain and upper pons are generally multiple and bilateral. Progression of this process results in brainstem dysfunction and death. Depending on the size and location of the ICH, intraventricular extension can occur and lead to the development of acute obstructive hydrocephalus or the later development of a chronic communicating hydrocephalus from impaired cerebrospinal fluid resorption. Some cases of thromboembolic stroke may be misclassified as ICH, because blood may extravasate and accumulate into large hematomas in areas of infarction. This secondary hemorrhage may be mislabeled if an early imaging study is not performed.

Clinical Manifestations

The clinical presentation of ICH is distinctive. In most cases, the onset is during the waking state when the patient is active; it is unusual for ICH to occur during sleep. The onset is abrupt, and the development of neurologic deficits occurs progressively over minutes to hours. This contrasts with the fluctuating or stepwise progression of deficits commonly seen in atherothrombotic infarcts, and with the appearance of maximal deficits at onset of cardioembolic strokes. In addition, prior TIA is rare with ICH and relatively common with ischemic stroke. The average age of onset of ICH, 50 to 70 years, is younger than that of other types of stroke. Patients may report lateralized headache; vomiting is common and nuchal rigidity may be present. Seizures are seen more frequently at the onset of ICH (17%) than in ICVD and are more likely to occur if the bleeding involves the cerebral cortex [40]. When first seen by a physician, 44% to 72% of patients are comatose.

The clinical presentation of ICH is monophasic, with symptoms rapidly progressing to maximum. Subsequent clinical deterioration is usually because of the effects of cerebral edema [41]; however, secondary bleeding and subsequent deterioration may also occur. It was recently suggested that thalamic hemorrhages may bleed further in patients
whose hypertension is not adequately controlled [42].

Diagnosis

The diagnosis of ICH can be made by CT scan, which provides accurate information about the size and site of the hematoma as well as the midline shift, and development of cerebral edema. Typically, the hemorrhage is hyperdense on CT scan during the acute phase, although severe anemia or ongoing hemorrhage may make the appearance more isodense or hypodense. The appearance of blood on the MRI scan varies because signal intensity is related to the state of degradation of the hemoglobin. This state changes with time; therefore, MRI is not the study of choice for initial imaging of ICH. In summary, deoxyhemoglobin is found in the first 3 days after ICH and is not well visualized on T1-weighted images but appears as an area of reduced signal intensity on T2-weighted images. Days 3 to 10 after ICH, methemoglobin appears as increased signal intensity of T1-weighted images, but the intracellular portion has reduced signal intensity on T2-weighted images. In the chronic state, the ICH has broken down to hemosiderin, which is poorly visualized on T1-weighted images but appears as reduced signal intensity on T2-weighted images. Magnetic resonance or conventional angiography should be considered for selected cases when an underlying aneurysm or arteriovenous malformation is suspected.

Lumbar puncture is contraindicated in acute ICH because of the risk of herniation from mass effect. Testing on admission for ICH should include coagulation profile and platelet counts for all patients, as well as bleeding time, if the patient is on aspirin.

Differential Diagnosis

Although the majority of ICH is from hypertensive or amyloid pathologies, other etiologies should always be considered. Ruptured arteriovenous malformation is an important cause of ICH, particularly for younger patients or those without risk factors for more typical causes. Secondary cerebral hemorrhage may occur after embolic infarction as the lodged embolus fragments and ischemic distal vessels may rupture with reperfusion. This is more common for patients with large embolic infarcts, in patients who are anticoagulated, and in patients with poorly controlled hypertension. ICH secondary to reperfusion may also occur after carotid endarterectomy.

ICH accounts for 0.5% to 1.5% of all bleeding events related to the use of oral anticoagulants. Oral anticoagulation increases the risk of ICH 8 to 11fold, compared to unanticoagulated patients. Compared with patients with spontaneous ICH, there is a trend toward larger hematomas and a higher mortality rate in patients on anticoagulants [43]. Cerebellar
hemorrhage is relatively common among anticoagulated patients, and mortality for these cases may be as high as 65%. Therefore among anticoagulated patients, the onset of focal neurologic signs, even if slowly progressive, necessitates CT scan to rule out ICH [44].

The use of fibrinolytic therapy, such as rt-PA, for coronary artery occlusion has also been associated with ICH, especially when adjunctive anticoagulant therapy is used. These cases have shown a predilection for the subcortical white matter and lobar areas, generally having a poor prognosis [45].

ICH associated with the presence of primary or secondary brain tumors is infrequent, accounting for only 2% of all cases of ICH. Higher-grade malignancies, such as glioblastoma multiforme, are more likely to bleed. The presence of thin-walled vessels in areas of neovascularization is thought to be the underlying reason for these hemorrhages. Metastatic lesions with the tendency to bleed include bronchogenic carcinoma, melanoma, renal cell carcinoma, and choriocarcinoma. ICH is frequent in hematologic disorders such as leukemia and reflects both the underlying thrombocytopenia and disseminated intravascular coagulopathy. When disseminated intravascular coagulopathy is caused by other organ failures, it can also lead to ICH.

Sympathomimetic drugs, such as methamphetamine, pseudoephedrine, and phenylpropanolamine, have caused ICH in the subcortical white matter. These agents are suspected of inducing vasculopathy with vasospasm or sometime a vasculitis. Cocaine, which blocks dopamine and norepinephrine reuptake, has been associated with ICH. Cocaine, especially crack cocaine, appears to incite cerebral vasospasm rather than a vasculitis. The secondary hypertension related to sympathetic stimulation may also cause ICH from any of these agents. This may explain the lack of abnormal angiographic findings among some of these cases [46,47], although recently cerebral vasospasm was demonstrated with MRA after acute cocaine administration [48]. Acute elevation of blood pressure in otherwise normotensive people, such as that which may follow migraine, is postulated to result at times in ICH.

Specific Syndromes of Intracerebral Hemorrhage

Hypertension related ICH tends to occur in stereotyped locations. In order of descending frequency, these locations are the putamen (30% to 50%), subcortical white matter (15%), thalamus (10%), pons (10%), and cerebellum (10%) [49].
ICH in the putamen is caused by bleeding from a lenticulostriate vessel. Clinically it is manifested by development of flaccid hemiplegia, hemisensory disturbances of all primary modalities, homonymous hemianopia, paralysis of conjugate gaze to the side opposite the lesion, and early alteration in level of consciousness. Subcortical aphasia may occur when a putamen hemorrhage involves the dominant hemisphere, and a hemineglect syndrome when it is on the nondominant side.

Thalamic ICH is characterized by a unilateral sensorimotor deficit in which sensory findings predominate. A variety of eye signs occur: Parinaud's syndrome; forced disconjugate down-gaze deviation medially on the side opposite the lesion; pseudoabducens paresis; and up-gaze paresis. The most specific localizing sign is inferomedial disconjugate gaze paresis contralateral to the side of the lesion. A permanent skew deviation, with vertical separation of images, may leave the patient with persistent diplopia. Owing to the location, thalamic ICH may rupture into the ventricular system.

Pontine ICH has the highest mortality. Quadriplegia, brainstem dysfunction, and small, unreactive pupils are seen at presentation and many patients rapidly develop coma. Bleeding typically arises from a paramedian branch of the basilar artery and almost always extends into the fourth ventricle. Cases of unilateral pontine ICH have a better outcome [50].

Cerebellar ICH most commonly involves the dentate nucleus (see Fig. 149.5). Alteration of consciousness is unusual at onset, but progressive deterioration with drowsiness typically occurs. The majority of patients initially manifest two of the following: (a) gait, truncal, or limb ataxia; (b) lower motor neuron facial paresis; and (c) an ipsilateral gaze palsy. Other common presenting signs and symptoms are headache, nausea, vomiting, vertigo, nystagmus, and limb ataxia [51]. Early surgical intervention is indicated for lesions larger than 3 cm or in smaller lesions with clinical progression, because cerebellar hemorrhage causes death in up to 60% of cases. Neurologic deterioration due to hemorrhage, causing obstructive hydrocephalus at the level of the fourth ventricle, is not uncommon. Surgical mortality is lower for patients who are still awake before operation; therefore, early intervention is indicated [51].
Approximately 3% of cases of ICH are primarily intraventricular in location. These events have minimal focal signs, but there may be loss of consciousness at onset. Hydrocephalus is a major complication [52].

**Treatment**

The acute medical management of ICH is aimed at correction of any predisposing systemic factors to prevent further clinical deterioration. Following ICH, there is a hematoma growth of 22% within the first 24 hours and hypertension is a major management problem in these cases. In response to the acute elevation of ICP caused by the hematoma, systemic blood pressure rises to maintain adequate cerebral perfusion pressure. This response, known as *Cushing’s reflex*, serves to protect the brain against ischemia, but autoregulation of cerebral blood flow can be
impaired after ICH or infarction. In patients with underlying chronic hypertension, the result may be excessively high blood pressure. The best management of this dilemma remains controversial. In chronic hypertension, the lower limit of cerebral autoregulation is shifted toward higher blood pressure; and acute lowering of systolic blood pressure is known to result in unfavorable decreases in cerebral perfusion pressure. Sustained hypertension in the acute phase of ICH, however, can lead to further bleeding or rapid accumulation of cerebral edema [49]. The recommended goal of systolic blood pressure in the acute phase of ICH is between 140 and 160 mm Hg [53]. Blood pressure should be lowered gently, and β-blockers are the agents of choice. Alternatively, a calcium channel blocker such as intravenous nicardipine may be useful because it does not elevate ICP like other vasodilators [49].

If the hematoma and associated cerebral edema raise ICP, clinical deterioration typically occurs. Acutely, hyperventilation effectively lowers ICP, but only for a matter of hours. Hyperosmolar agents, such as mannitol, sorbitol, and glycerol, can provide more sustained reductions in ICP. Their utility remains unclear and the osmotic diuresis induced by these agents can lead to dehydration, electrolyte imbalances, and pulmonary edema if the patient is not actively managed. Treatment of ICH with steroids can be detrimental to overall outcomes, so they are not routinely administered [54]. The value of ICP monitoring in these situations remains controversial. Elevation of ICP owing to hydrocephalus is treated with ventricular cerebrospinal fluid diversion. Anticonvulsants are not routinely used in ICH. If seizures are not present at onset, patients are generally at low risk for developing seizures, but hemorrhage into the cortex, regardless of site of origin, predisposes to seizures. Subarachnoid or intraventricular extension of bleeding does not increase the risk of seizures. Seizures have been noted with hemorrhages in the caudate but not with putaminal or thalamic events. Although the incidence of chronic epilepsy from ICH is low (6.5% to 13.0%), any seizures usually begin within the first 2 years after the event [55]. Prophylaxis against peripheral venous thrombosis should be accomplished with pneumatic boots.

After the patient is acutely stabilized, angiography may be performed if there is no history of hypertension or the bleeding is in an atypical location. This is particularly important or pertinent for younger patients, in whom a larger percentage of cases of ICH are caused by underlying vascular lesions, such as arteriovenous malformation or aneurysm. At present, surgery may be indicated for lobar ICH in which the patient
continues to deteriorate, and for cerebellar ICH. Emergency ventriculostomy to relieve hydrocephalus should be considered if this condition develops acutely. Surgical intervention for putaminal ICH remains controversial; it is inappropriate for thalamic and pontine hemorrhages.

The prognosis for ICH is worse for larger lesions. By location, pontine ICH has the highest mortality, followed by cerebellar and then basal ganglia lesions. Lobar ICH carries the most favorable outlook for survival and functional recovery [43]. Clinical scoring systems can provide insight into mortality and disability risk, important considerations for clinicians and patients with their families alike [56,57]. The ICH score estimates risk of death by 30 days and is predicated on patient age, admission Glasgow Coma Scale (GCS) score, hemorrhage size, intraventricular extension, and infratentorial origin of bleeding (Table 149.6).

ICH, intracerebral hemorrhage; GCS, Glasgow Coma Scale.
ICH can be neurologically devastating. Patients with ICH often require an ICU setting because of the severity of disease, particularly when it is complicated by markedly increased ICP. Treatments remain supportive, directed at attenuating complications and promoting recovery. Although ICH is more severe than ICVD, many patients have significant recovery with expert supportive care, and restorative and rehabilitative efforts (Table 149.5).

Subarachnoid hemorrhage (SAH) results from bleeding into the cerebrospinal fluid (CSF)-filled cisterns between the arachnoid and pia mater (Fig. 150.1). The treatment, complications, and prognosis vary according to the underlying cause of the hemorrhage. A ruptured cerebral aneurysm is the most common and best-studied form of SAH, accounting for 3% of all strokes [1]. SAH is a neurologic emergency requiring urgent management and intensive care unit (ICU) level of monitoring. Improvements in functional outcomes are owing to early recognition, intervention, and intensive care management to limit the risks of rebleeding, consequences of cerebral vasospasm (cVSP), and medical complications.
of a large SAH from a ruptured berry aneurysm, resulting in blood in all major cisterns, interhemispheric and sylvian fissures, and both ventricles. Mild obstructive hydrocephalus is also present, as visible by the slightly dilated temporal horns (white arrows).
SAH incidence and mortality are lower for Caucasians than other racial groups [1]. The overall incidence is 9 per 100,000 person per year and progressively increases with age up to 31 per 100,000 person per year after the age of 85 for all types of SAH combined. The median age of the most common form of SAH, the aneurysmal type, is 53 years [1]. SAH is a female-predominant disease, with two-thirds of SAH patients being women [2]. Mortality rate from a ruptured aneurysmal subarachnoid hemorrhage (aSAH) varies between 32% and 44%, with early rebleeding carrying the highest risk of mortality [3].
Saccular (berry) aneurysms lack the normal muscular media and elastic lamina layers, making it more vulnerable to rupture. Eighty-five percent of saccular aneurysms are located in the anterior circulation and 15% are in the posterior circulation [4]. Common sites for aneurysms are at the junction of the anterior cerebral and anterior communicating arteries, the origin of the posterior communicating artery, the middle cerebral artery trifurcation, and at the top of the basilar artery. 20% to 30% of patients have multiple aneurysms. Several connective tissue diseases such as polycystic kidney disease, Marfan syndrome, Ehlers–Danlos syndrome type IV, Neurofibromatosis Type 1, fibromuscular dysplasia, and coarctation of the aorta are associated with an increased incidence of intracerebral aneurysms [4,5]. Seven to 20% of patients with aSAH have first- or second-degree relatives with intracranial aneurysms [4]. Familial intracranial aneurysms, as well as the increased frequency of other familial syndromes, lend support to the congenital theory. Using modern genomic analysis, multiple genetic loci associated with the presence of cerebral aneurysms have been and continue to be identified [6]. Important risk factors include later age of onset, hypertension, cigarette smoking, alcohol consumption, amphetamine, or cocaine use. These factors may contribute to aneurysmal formation and expansion through degenerative processes [4].

Non-aSAH is determined based on the failure to illustrate an aneurysm on initial as well as repeat imaging studies, or when another etiology has been identified (Fig. 150.2). Common causes include vascular malformation, traumatic SAH, cerebral amyloid angiopathy, and Reversible Cerebral Vasoconstriction Syndrome (RCVS) [7]. The clinical presentation is often similar to that of aneurysmal SAH.
These noncontrast head CT from two different patients show high frontal–parietal nonaneurysmal SAH filling the sulci in a localized area (circles). Both SAH were spontaneous, and repeat cerebral angiography was negative in both cases. Some nonaneurysmal SAH can be subtle (as in these two patients); therefore, the head CT must be reviewed carefully, especially when there is a convincing clinical history of a sudden onset of headache.

Perimesencephalic SAH refers to the collection of blood in the subarachnoid space centered on the basal and suprasellar cisterns around the pons and the midbrain (Fig. 150.3). When a ruptured aneurysm cannot be identified as the cause of the bleed, this distribution of subarachnoid blood is thus known as nonaneurysmal perimesencephalic SAH. It represents 5.8% of all SAH, often lacks identification of a specific cause and commonly follows a rather benign course [7,8].

This noncontrast head CT from a single patient with perimesencephalic SAH reveals blood in the perimesencephalic and prepontine cisterns (white arrows) only. This patient’s cerebral angiogram was repeated twice, and never revealed any source of bleeding.
CLINICAL PRESENTATION

A “sentinel” (warning) hemorrhage occurs among approximately 20% of patients and is characterized by headache or meningismus that lasts at least 48 hours in 70% of cases. The event is misdiagnosed in 20% to 40% as tension headache, migraine, sinusitis, viral syndrome, aseptic meningitis, or malingering [9]. Evidence of a warning leak must be treated with a high index of suspicion because such events precede major hemorrhage. Neurologic and functional outcomes are greatly improved if the patient is treated while neurologically intact before a major rehemorrhage [10].

SAH produces severe headache (maximum at onset, “worst headache of life”), neck pain, nausea and vomiting, dizziness, diplopia, photophobia, and lethargy. At the time of rupture, 45% of patients lose consciousness and may demonstrate abducens nerve palsies, reflecting the acute rise in intracranial pressure (ICP) that may transiently equal or exceed mean arterial pressure [11]. Early seizures after SAH (8% to 11%) reflect a rise in ICP but are not indicative of the site or severity of rupture [12,13].
Several clinical grading scales have been developed to assess the severity and prognosis based on the initial presentation. The grading scale developed by Hunt and Hess [14] is useful in correlating the patient’s clinical status with prognosis (Table 150.1). Grades I and II at presentation have a relatively good prognosis, grade III has an intermediate prognosis, and grades IV and V have a poor prognosis. The Hunt and Hess scale, however, is clinically used only in the United States, although the rest of the world has adopted the World Federation of Neurological Surgeons scale (WFNS) [15]. The WFNS uses the combined Glasgow Coma Scale along with clinical motor deficit to estimate the likelihood of poor outcome (Table 150.2).

Serious systemic disease such as hypertension, diabetes, severe arteriosclerosis, chronic pulmonary disease, and severe vasospasm seen on arteriography, result in placement of the patient in the next less favorable category.

TABLE 150.2 World Federation of Neurological Surgeons Scale
The radiologic Fisher Score was developed in 1981 using first-generation head CT to estimate the risk of symptomatic vasospasm based on the blood distribution pattern on the initial CT [16]. Major disadvantages of the original Fisher Score were its nonordinal increase in the vasospasm risk, making it nonintuitive to use at the bedside, as well as that it was difficult to incorporate into statistical models used in the research. Therefore, the score has been revised and validated using modern-technology head CT in a much larger number of patients, and is now known and routinely used as the Revised Fisher Score [17]. Its linear increase in vasospasm risk based on SAH clot thickness and the presence or absence of intraventricular hemorrhage (IVH) makes it the preferred radiologic score in current use (Table 150.3).

SAH, subarachnoid hemorrhage; IVH, intraventricular hemorrhage.
When SAH is suspected, an urgent noncontrast head CT should be obtained to identify, localize, and quantify the hemorrhage. The sensitivity of a noncontrast CT head reaches almost 100% in the first 6 to 12 hours and remains over 90% sensitive at 24 hours when interpreted by an experienced physician [18,19]. The sensitivity progressively declines with time to around 50% at 5 days. When a noncontrast CT head is nondiagnostic and the clinical suspicion of SAH remains high, an urgent lumbar puncture is indicated. The diagnostic finding is xanthochromia, a yellowish appearance of the CSF following centrifugation. This is the result of blood product degradation that is detected ≥2 hours after the onset of SAH and remains detectable in the CSF for up to 2 weeks. Protein may be elevated and glucose may be very slightly depressed. Opening pressure at the time of lumbar puncture may reflect the elevation of ICP.

CT-angiogram is the preferred noninvasive study to identify an aneurysm in the emergent setting with sensitivities and specificities nearing over 98% [20,21]. Magnetic resonance angiogram (MRA) can be particularly helpful to diagnose SAH several days after symptom onset when a head CT may be negative. MRI, however, is less readily available and more time consuming [22].

Four-vessel cerebral angiography remains the gold standard and is necessary to localize the lesion, assess vasospasm, and the possible presence of multiple aneurysms (Fig. 150.4). It should be performed as soon as possible after initial hemorrhage, because endovascular treatment can commonly be provided simultaneously (Fig. 150.5). If angiography does not reveal an aneurysm, angiography may be repeated in 1 to 3 weeks; an intraluminal thrombus or extraluminal compression of a small aneurysm by subarachnoid clot can acutely interfere with angiographic visualization of aneurysms [23].
FIGURE 150.4  Shown is a 3D reconstruction of a large anterior communicating artery aneurysm (arrows). The advantage of 3D reconstruction techniques include a high-resolution view of the aneurysm to visualize smaller, penetrating arteries coming off the aneurysm versus parent vessel, as well as the ability to visualize smaller aneurysms and infundibulum-like outpouchings. Without 3D reconstructions, these could potentially be missed.

FIGURE 150.5  Shown is the cerebral angiography of the same patient from Figure 150.4, which reveals an anterior communicating artery aneurysm, precoil and postcoil (arrows). After coiling, the aneurysm no longer fills. Although it appears that there may be a filling defect, it is merely the coil mass overlying the parent vessel in the anterior–posterior 2D view.
ANEURYSM MANAGEMENT

SAH is instantly fatal in 12% of cases [24] while the 28-day mortality is 35% [25]. In-hospital mortality is 18% [26]. The high mortality is due to further complications including rebleeding, delayed cVSP causing infarction, hydrocephalus, increased ICP, seizures, and medical complications such as myocardial infarction, stress cardiomyopathy, and neurogenic pulmonary edema [26].

After SAH, the initial goals of treatment are aimed at identification and early aneurysm treatment, by either coiling or clipping. The International Subarachnoid Aneurysm Trial (ISAT) concluded that patients receiving coiling were more likely to be alive and independent at 10 years compared to patients having undergone surgical clipping, albeit with a very low increased risk of rebleeding deemed not to outweigh the benefit [27]. One downside of coiling is the higher aneurysm recurrence rate on follow-up angiogram 6 months or longer after the initial coiling, sometimes requiring repeat coiling [27]. Based on ISAT, the endovascular treatment of intracranial aneurysms, rather than the surgical approach, is now the preferred treatment option [3].
NEUROLOGIC COMPLICATIONS

Rebleeding

Rebleeding is a serious and frequent complication of SAH. The rebleeding risk is 5.8% in the first 24 hours after aSAH and carries a 57% mortality [28]. Clinical symptoms include sudden increase in headache, seizure, nausea, vomiting, depressed level of consciousness, and new neurologic deficits. A well-recognized risk factor for rebleeding is hypertension and the fluctuation of blood pressures. Although a relatively elevated blood pressure could promote rebleeding, low blood pressure may diminish cerebral perfusion, especially in the setting of high ICP. Prior to securing the aneurysm, systolic blood pressure < 160 mm Hg has been recommended [29], with the necessity to titrate on a case-by-case basis factoring in any signs of cerebral hypoperfusion. The blood pressure should be lowered gently and is best managed with short acting agents such as nicardipine or labetalol [30].

cVSP and Delayed Cerebral Ischemia

cVSP and subsequent delayed cerebral ischemia (DCI) are a major cause of morbidity and mortality post-SAH. Only symptomatic, but not angiographic or transcranial Doppler (TCD)-detected cVSP, has been associated with DCI, and therefore considered the clinically meaningful type of cVSP [31].

  cVSP is evident on TCD for 71% of patients and by angiogram for 60% of patients [32], but it causes clinically evident symptoms in only 36% [33]. This difference probably reflects the adequacy of collateral circulation in the individual patient, the degree of vessel narrowing and the involvement of less critical brain structures. Unlike rebleeding, the clinical presentation of cVSP occurs progressively over a period of hours to days. It may be apparent as early as the third day after hemorrhage, with a peak between days 4 and 12, and rarely as long as 3 weeks after SAH [34].

  Monitoring for cVSP includes frequent neurologic examinations, and daily or every-other-day TCD monitoring. Trends in the TCD from baseline early after SAH onset are clinically useful because an elevated blood flow velocity is often detected before the occurrence of symptomatic vasospasm. Disadvantages include diagnostic precision that is operator dependent, and much lower sensitivities for vessels other than the middle cerebral artery.

  Although the calcium-channel blocker nimodipine has failed to prevent
cVSP, it improves morbidity from vasospasm, and is the only therapeutic agent with level I evidence to support its use post-SAH [35]. The current standard of care is to administer prophylactically 60 mg of nimodipine orally every 4 hours for a 21-day course beginning at the onset of all aneurysmal SAH. The main adverse effect is mild transient hypotension.

“Triple H” (hypervolemic, hypertensive, and hemodilutional) therapy is no longer supported by guidelines, owing to the existing evidence of adverse associations with outcomes after the use of hemodilution [36]. Prior to the onset of symptomatic cVSP, maintaining a euolemic state without prophylactically induced hypertension is now recommended [3]. Once symptomatic cVSP occurs, “HH-T” (hypertensive and hypervolemic therapy) is indicated. Elevation of systemic arterial pressure produces a significant increase in regional cerebral blood flow [37], while optimal increase in the amount of blood pressure, or the use of systolic versus mean arterial pressure thresholds are not known.

Intra-arterial infusion of vasodilators such as verapamil, nicardipine, and milrinone [38,39] or, in refractory cases, angioplasty, are other commonly used endovascular techniques for treatment of cVSP [40]. Patient selection criteria for treatment include the presence of clinically symptomatic cVSP without infarction in a patient with a repaired aneurysm.

The severity of cVSP and subsequent ischemia appears to relate to the amount of blood in the CSF space [41]. Thus, there is significant interest in the therapeutic drainage of bloody CSF. To achieve this, a ventriculostomy is commonly placed. In Europe, an additional lumbar drain is often placed [42,43], but due to the lack of large trials this practice has not been established as routine in the US. The experimental use of intrathecal or intraventricular urokinase or tissue plasminogen activator has suggested improved outcomes and a lower incidence of angiographic cVSP and infrequent complications [44], although the trials thus far have been underpowered.

Seizures

Seizures may increase ICP and may subsequently increase the risk for rebleeding. A middle cerebral artery aneurysm and a thick SAH blood clot may increase the risk of developing seizures, which is as high as 27%, and is the highest within the first day [45]. Use of prophylactic anticonvulsants such as phenytoin or levetiracetam is indicated prior to securing the aneurysm. Studies of the use of anticonvulsants, in particular phenytoin, have been implicated in worse neurologic recovery [46,47], and therefore guidelines recommend stopping the anticonvulsants as soon as the aneurysm has been secured, as long as the patient is not comatose and has a consistent neurologic examination to
follow [3]. Continuation of anticonvulsants may be justified when the patient had seizures at SAH onset, or is thought to be at very high risk.

Hydrocephalus

Hydrocephalus can develop acutely within the first 24 hours after SAH because of impaired CSF resorption at the arachnoid granulations or the presence of an intraventricular clot obstructing CSF outflow [48]. Clinically significant hydrocephalus developing subacutely over a few days or weeks after SAH is manifested by impairment of vertical gaze and progressive lethargy. Ventricular CSF drainage is indicated when the clinical neurologic examination deteriorates. Although ventriculostomy or lumbar punctures should be performed with caution in patients with an unsecured aneurysm, it does not seem to be associated with a significant increased risk of rebleeding [49]. A delayed form of hydrocephalus manifested by cognitive changes and gait disorders may be observed several weeks after the SAH; in these cases, a ventriculoperitoneal shunt may be indicated [50].

Cardiac and Pulmonary Complications

Cardiac and pulmonary complications may be seen in high grade SAH in the first few days after aneurysm rupture [51,52]. Excessive sympathetic stimulation (sympathetic surge) at the time of aneurysm rupture leads to cardiac dysrhythmias in 28% of SAH cases [53]. The increased levels of circulating catecholamines influence the α-receptors of the myocardium and can result in prolonged myofibril contraction, eventually causing myofibrillar degeneration and necrosis. Elevated levels of serum troponin and brain natriuretic peptide levels are common, but not due to coronary artery plaque rupture with thrombocyte activation and adhesion. SAH is the most frequent neurologic cause for neurogenic electrocardiographic changes: large upright T waves, inverted T waves, prolonged QT intervals, prominent U waves and minor ST elevation or depression can occur. Despite ST–T changes, the incidence of myocardial ischemia remains low [53,54]. Pathologic Q waves are not common in SAH and suggest the need for further investigations for myocardial infarction.

The sympathetic surge also leads to stress cardiomyopathy and a global compromise in cardiac left ventricular (LV) function. This usually transient cardiomyopathy is characterized by global dysfunction not respecting the coronary arteries vascular territory and results in “apical ballooning,” giving the cardiac silhouette the shape of a Japanese octopus.
fishing pot, hence the name “Takotsubo” cardiomyopathy. In rare instances, an intra-aortic balloon pump may be indicated during this transient cardiac dysfunction [55].

Neurogenic pulmonary edema is not uncommon with high grade SAH [52]. It is due to direct β-receptor stimulation in the lung during the sympathetic surge. This can lead to sudden and early massive increase in pulmonary lung water, with severe hypoxemia. Although the pulmonary edema is transient during the first 24 to 48 hours, early recognition and treatment with diuretics may be life saving [56].
GENERAL ICU MANAGEMENT

Once the aneurysm has been secured, general ICU management includes close neurologic and hemodynamic monitoring, head elevation to improve cerebral venous return and prevent increased ICP and good pulmonary toilet to avoid atelectasis and pneumonia.

Headache often persists for several weeks, even after securing the aneurysm, and is due to meningeal irritation (chemical meningitis) from the blood product breakdown. Pain control can be difficult, and narcotics are commonly required. In refractory pain, corticosteroids (dexamethasone) may help improve the meningitic symptoms.

Hyponatremia is found among 30% of SAH cases [57]. It is caused by hypothalamic dysfunction, sometimes causing the syndrome of inappropriate antidiuretic hormone (SIADH), but much more commonly cerebral salt wasting (CSW) owing to an increase in circulating brain natriuretic peptide levels. Serum sodium levels, osmolality as well as the volume status must be followed closely. The usual treatment for SIADH is fluid restriction; however, this is contraindicated in SAH, because it may exacerbated cVSP, and hypertonic saline should be used instead while maintaining euvoemia [58]. CSW is a hypovolemic hyponatremic state that responds to treatment with isotonic fluids and fludrocortisone [59].

Venous thromboembolism (VTE) prophylaxis should be started immediately on admission with the use of pneumatic compression boots. Although all antiplatelet and anticoagulation medication should be discontinued on admission, they should be restarted if still medically indicated along with subcutaneous fractionated or unfractionated heparin for VTE prophylaxis as soon as the aneurysm is secured. With decreasing platelet counts, one should have a high degree of clinical suspicion for heparin-induced thrombocytopenia type II, because it affects 6% of SAH patients [60].

Fever is a very common complication of SAH and it is associated with worse outcomes [61]. Although fever is, therefore, commonly treated with induced normothermia, one should note that no clinical trials have been conducted to show improved outcome by applying normothermia and suppressing fever. Anemia and hemoglobin concentration less than 9 g per dL have been associated with worse outcome as well; however, optimal hemoglobin goal levels are not known [62,63]. Hyperglycemia of >200 mg per dL is also associated with worse outcome but should be treated with strict avoidance of hypoglycemia [64].
HIGH-VOLUME SAH CENTERS

It is noteworthy that multiple studies have shown improved survival and overall outcomes when patients are treated in high-volume SAH treatment centers, defined as a yearly volume of >35 SAH patients per year \([65,66]\). Therefore, when feasible, direct admission, or transfer to a high-volume center with an experienced multidisciplinary team is strongly recommended \([3]\).

Utility of Ultrasonography for Management of SAH

Neurogenic stunned myocardium (NSM) is a triad of transient LV dysfunction, elevation in cardiac enzymes, and electrocardiogram changes that may occur with SAH \([67]\). The intensivist who is competent in goal directed echocardiography (see chapter on critical care echocardiography) is able to establish the diagnosis at point of care.

Echocardiography Findings of NSM (Takotsubo Cardiomyopathy)

The usual pattern of abnormality is systolic wall motion abnormality that involves the apical LV segments with sparing of the mid and basal segments of the myocardium. The apical hypokinesis may be severe with akinesis or dyskinesis of the involved segments. Because the base of the heart continues to contract, the apical dyskinesia results in a pattern of apical ballooning during systole. Because the predominant abnormality is apical in position, the abnormality may not be apparent on the parasternal long axis view. The apical four-chamber and subcostal long axis views reveal the characteristic abnormality (Video 29.8 in Chapter 29 Echocardiography as a Monitoring Tool in the ICU).

Atypical patterns of NSM include segmental wall motion abnormalities involving the basal and mid ventricular myocardial segments resulting in an inverted Takosubo pattern where the apical segments exhibit normal contractility while the basal segments have reduced systolic function \([68,69]\). Abnormalities of right ventricular function have been described as well \([70]\).

Echocardiography cannot distinguish between NSM and myocardial
ischemia/infarction, as both entities result in segmental wall abnormalities. Echocardiographic findings support the diagnosis NSM, but clinical correlation is required for definitive diagnosis. Advanced echocardiographic measurements such as diastolic function, speckled tracking, and MRI/echocardiographic reveal characteristic abnormalities, but are not required for diagnosis [71–73]. Goal directed echocardiography examination is effective in identifying the characteristic features of NSM.

### Summary of Recommendations

DEFINITION AND CLASSIFICATION

Status epilepticus (SE) is a condition in which there is “failure of the ‘normal’ factors that serve to terminate a typical generalized tonic-clonic seizure” [1,2]. SE is defined as 5 minutes of continued seizure activity, or two or more seizures with incomplete recovery between. SE is usually divided into:

- **convulsive SE**, where the patient does not regain consciousness between repeated generalized tonic–clonic attacks;
- **focal SE** without altered cognition, behavior, or consciousness [3], characterized by continuous or repetitive focal seizures without loss of awareness [4]; and
- **nonconvulsive SE** (NCSE), which includes generalized forms such as absence SE, and focal SE with behavioral features, (previously called complex partial SE). NCSE is also used to describe continued seizure activity in patients who are comatose, but have few other clinical signs.

Convulsive Status Epilepticus

Most generalized tonic–clonic SE consists of focal seizures that have generalized secondarily; genetic seizures uncommonly generalize [2,5]. Most patients do not convulse continuously, but a few minutes of seizures are followed by prolonged unconsciousness leading to the next seizure. During convulsive SE, massive autonomic discharge occurs with tachycardia and hypertension. Corneal and pupillary reflexes are lost and plantar reflexes may be extensor. As SE continues, the motor manifestations may evolve into more subtle activity such as focal twitching, nystagmus, eye deviation, or recurrent pupillary hippus [4].
Among patients who are very encephalopathic, SE may also present in this more subtle form, without initial convulsive activity; electroencephalography (EEG) is required to confirm the diagnosis. Myoclonic SE with repetitive, asynchronous myoclonus with variable clouding of consciousness is often classified as a form of convulsive SE and may evolve into generalized tonic–clonic SE. In adults, myoclonic syndromes are usually caused by toxic or metabolic encephalopathies, most commonly severe cerebral anoxia [6]. The patients are usually comatose, and the prognosis is poor.

**Focal Status Epilepticus Without Altered Cognition, Behavior, or Consciousness (Dyscognitive Features)**

Focal SE without dyscognitive features is the second most common form of SE, after generalized tonic–clonic SE [4]. In focal motor SE, clonic activity is localized usually to the face or an extremity. This activity may spread, corresponding to the somatotopic organization of the motor cortex, known as a Jacksonian march. Alternatively, the focal motor seizures may be multifocal, often precipitated by metabolic disorders, such as hyperglycemia with a hyperosmolar nonketotic state [7]. *Epilepsia partialis continua* is a form of focal motor SE characterized by continuous, highly localized seizures that do not become generalized and in which consciousness is maintained.

**Nonconvulsive Status Epilepticus**

NCSE is an underrecognized cause of coma. In a recent study, NCSE was present in 8% of all comatose patients, without signs of seizure activity [8]. In other studies, a third of patients with unexplained altered mental status in intensive care units (ICUs) were in NCSE. NCSE is more likely to occur in the setting of acute medical problems, both systemic and neurologic [8–10].

NCSE includes absence SE and focal SE with dyscognitive features [4]. Clinically, both present with a prolonged period of altered behavior and can masquerade as a psychiatric fugue state. NCSE is defined as a prolonged confusional state of 30 minutes or longer, involving a variable level of altered consciousness [8]. Absence SE may be accompanied by subtle myoclonic movements of the face; eye blinking; and occasional automatisms of the face and hands. The EEG is diagnostic, revealing generalized spike/slow wave activity. Focal SE with dyscognitive features involves a series of focal seizures with staring, unresponsiveness, and motor automatisms, separated by a confusional state, or a more prolonged state of partial responsiveness and semipurposeful automatisms. The EEG usually shows more focal continuous epileptiform
activity, but if an EEG shows rhythmical slowing with subtle clinical signs as described above, or there is an evolution of the EEG pattern, NCSE should be considered [11].
ETIOLOGY

Some of the major etiologies of SE are shown in Table 151.1. Symptomatic SE, resulting from an acute or chronic neurologic or metabolic insult, is at least twice as common as idiopathic SE (presumed genetic etiology for the seizures in an otherwise neurologically normal person) [5]. In adults, a major cause of SE is stroke (up to 22% of cases) or decreasing antiepileptic drugs (AEDs) (up to 34% of cases) [2]. Other etiologies include autoimmune encephalitides—either limbic encephalitis or diffuse encephalitis—and may have a paraneoplastic or nonparaneoplastic cause [12]. New-onset refractory SE (NORSE) refers to bouts of refractory status epilepticus due to unknown causes, some of which were proven to be either infectious or autoimmune in etiology [13].

PROGNOSIS AND SEQUELAE OF STATUS EPILEPTICUS

Mortality for SE depends on the specific etiology; duration of the episode; and the age of the patient \[2,5\]. Anoxia has been associated with the highest mortality; and alcohol withdrawal and AED discontinuation with low mortality rates. Patients with idiopathic SE have a low mortality rate. The duration of SE longer than 30 minutes and age over 70 significantly increases mortality \[5,14\]. Despite improved medical care, convulsive SE still has an overall mortality rate of 20\% \[2,15\]. The mortality of focal SE with dyscognitive features was 18\% in one study \[16\]. Other adverse outcomes include intellectual deterioration, permanent neurologic deficits, and chronic epilepsy.

SE itself can produce profound neuronal damage. Neuropathologic studies of the brains of children and adults who died shortly after SE reveal ischemic neuronal changes in the hippocampus; middle layers of the cerebral cortex; cerebellum (Purkinje cells); basal ganglia; thalamus; and hypothalamus \[17\]. These changes mimic those of severe hypoxia or hypoglycemia. Hyperthermia during an episode of SE has also been shown to correlate closely with the degree of central nervous system (CNS) damage \[18\].

The perpetuation of SE is caused by an imbalance between excitotoxic (glutamate mediated) and inhibitory (\(\gamma\)-aminobutyric acid [GABA] mediated) mechanisms \[15,16\]. Downregulation of GABA receptors, or excitotoxic mechanisms involving glutamate receptors—both NMDA (N-methyl-D-aspartate) and non-NMDA receptors—are involved \[2,15,19\]. Calcium influx during excitation is a critical component of neuronal injury and cell death, with activation of proteases and lipases, leading to degradation of intracellular elements \[19\].

Abnormal neuronal activity alone can cause permanent neurologic injury; patients with focal dyscognitive or focal motor SE without concomitant hypotension, hypoxia, or hyperpyrexia can still have subsequent neurologic injury in the region of the brain associated with the seizure. Chronic memory impairment may follow focal dyscognitive SE \[20\], and focal neuronal necrosis (and edema) in the region of the brain involved with seizure activity has been found after focal motor status \[21,22\]. Focal magnetic resonance imaging (MRI) changes are seen
after prolonged epileptic activity, particularly on diffusion-weighted and perfusion MRI, though these changes may dissipate over time [23]. Mortality in NCSE with preexisting epilepsy is lower compared to NCSE following an acute medical condition [8].
SYSTEMIC COMPLICATIONS

If convulsive SE is not terminated promptly, secondary metabolic and medical complications may occur (Table 151.2). Hyperthermia may follow excessive muscle activity and hypothalamic dysfunction, or may be caused by an underlying infection responsible for the initiation of SE. Both hyperthermia from an infection and that from SE can be accompanied by peripheral leukocytosis [17] due to demargination, with a white blood cell count in the range of 12,700 to 28,000 cells per μL. The differential may be normal or may show lymphocytic or polymorphonuclear predominance, but band forms are rarely present. A mild cerebrospinal fluid (CSF) pleocytosis can occur with SE [17]; the maximum cell count is usually less than 80 cells per mm$^3$, with an initial polymorphonuclear predominance that reverts to a lymphocytic predominance as the pleocytosis resolves over a few days. Mild transient elevations of CSF protein may also occur. Lowering of the CSF glucose level does not occur, and reduced CSF glucose immediately raises concern for an underlying infectious or inflammatory process.

muscles results in metabolic acidosis within minutes after the start of SE, with a variable respiratory contribution to the acidosis from carbon dioxide retention. The degree of acidosis does not correlate with the extent of neuropathologic damage. After cessation of the seizure, lactate is rapidly metabolized, resulting in spontaneous resolution of the acidosis. Systemically, hyperglycemia initially develops owing to catecholamine and glucagon release; later, hypoglycemia occurs due to increased plasma insulin, increased cerebral glucose consumption, and excessive muscle activity.
DIAGNOSIS

SE is a medical emergency and must be treated immediately in a critical care setting. Pharmacologic intervention is more effective at an early stage of SE than after a delay \([2,8,15,19,24,25]\). Treatment must be fourfold: termination of seizures; prevention of recurrent seizures; identification of etiology; and treatment of complications.

The initial step is to confirm the diagnosis. A flurry of seizures separated by a normal level of consciousness does not constitute SE (although urgent treatment may still be required). NCSE may present clinically with a change in mental status only. As mentioned earlier, in this setting NCSE appears to be greatly underdiagnosed.

For diagnosis of NCSE, certain well-defined EEG criteria need to be met. These are (1) repetitive epileptiform activity at more than 2.5 per second or (2) repetitive epileptiform or rhythmic slow activity less than 2.5 per second and fulfilling secondary criteria, defined as (1) clear clinical and EEG improvement after intravenous (IV) antiepileptic medication; (2) associated subtle clinical ictal signs; or (3) evolution in frequency, morphology, or location of EEG activity \([11]\).
INITIAL ASSESSMENT

Once a diagnosis of SE is made, it is important to perform a rapid initial assessment of medical stability and workup of potential etiologies (Table 151.3). Obtain as much history as possible within the first few minutes, including any history of a preexisting chronic seizure disorder and AED use; alcohol or drug abuse; or any recent neurologic insult. The examination should focus on signs of systemic illness (e.g., uremia, hepatic disease, and infection); illicit drug use; evidence of trauma; or focal neurologic abnormalities. After appropriate blood samples have been obtained, glucose administration is recommended. Hypoglycemia is a rare but easily reversible cause of SE. Because glucose administration may precipitate Wernicke–Korsakoff syndrome in some individuals with marginal nutrition, thiamine should also be given. Subsequent IV infusions should consist of saline solution, because some AEDs precipitate in glucose solutions. The patient must be assessed for other metabolic consequences of status. Hyperthermia should be treated and oxygenation must be maintained. The metabolic acidosis that occurs does not adversely affect neurologic outcomes and does not need treatment with bicarbonate [26]. Blood pressure must be carefully monitored; the systemic hypertension and decreased cerebrovascular resistance of early SE provide adequate blood flow for the increased metabolic demand in the brain, but eventually hypotension may occur, making the brain vulnerable to inadequate perfusion. Pharmacologic intervention for the seizures can exacerbate any hypotension.

It is essential to determine whether a metabolic disorder is causing the SE; if this is the case, pharmacologic intervention for SE alone is not effective. Systemic and CNS infections must be excluded, and lumbar puncture is often necessary. A contrast-enhanced head CT scan can be useful after the patient has been medically stabilized. MRI is preferred for suspected small or subtle lesions but may not be practical in the emergent setting.

TABLE 151.3 Management Guidelines for Generalized Status Epilepticus in Adults

<table>
<thead>
<tr>
<th>Time (min)</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>0–9 min:</td>
<td>If diagnosis is uncertain, observe for: recurrence of generalized seizures without intervening recovery of consciousness; continuous seizure activity &gt;5 min. ABCs</td>
</tr>
</tbody>
</table>

**Note:** ABCs refer to Airway, Breathing, Circulation.
Establish airway; pulse ox; administer O2; cardiac monitor.

Establish IV access (NS or saline lock), bedside rapid glucose determination. If hypoglycemic, give glucose (D50) 50–100 mL and thiamine 100 mg IV.

Labs: CBC/diff, electrolytes, BUN/Cr/Glu, anticonvulsant drug levels, toxicology screen, other labs as indicated by history/examination (including testing for pregnancy).

5–30 min:
Within 10 minutes:
Lorazepam 0.1 mg/kg IV (<2 mg/min), given 2 mg at a time or midazolam 10 mg IM (or diazepam 0.1–0.2 mg/kg, up to 10 mg per dose, <2 mg/min).

Within 30 minutes:
Phenytoin 20 mg/kg IV at ≤50 mg/min (fosphenytoin 150 mg PE³/min), slower rate in elderly or if hypotension or bradycardia develop. Draw blood for level 10 min after infusion complete.

- Cardiac monitoring; frequent BPs; careful observation of respiratory status; andoximetry.
- EEG monitoring, if possible.
- Consider additional 5 mg/kg boluses of phenytoin to a maximum dose 30 mg/kg if seizures persist.
- Lorazepam as needed for seizures during phenytoin load.

Alternatives for Phenytoin or if seizures continue:
Levetiracetam 20–60 mg/kg IV at 2–5 mg/kg/min IV.
Valproate sodium 20–30 mg/kg IV at 3–6 mg/kg/min, an additional 20 mg/kg may be given 10 min after loading infusion. Watch for hyperammonemia, pancreatitis, thrombocytopenia, and hepatotoxicity. Known teratogen.
Phenobarbital 20 mg/kg IV load, ≤100 mg/min. Anticipate respiratory depression and need for intubation. Consider for alcohol withdrawal.
Lacosamide 200–400 mg IV over 3–5 min. Adverse effects: prolonged PR interval; first degree AV block; and bradyarrhythmia.

31–90 min:
For persistent status: induce coma. Intubate if not previously done.
Continuous EEG to monitor for seizures and level of anesthesia.
Propofol 1–2 mg/kg IV bolus, 1–5 mg/kg/h infusion. Note: 5 mg/kg/h = 83 mcg/kg/min. Monitor serum for lactate, triglycerides, CPK, and BUN/Cr.
OR
Midazolam 0.2 mg/kg IV bolus, infusion 0.1–2.0 mg/kg/h (tolerance after 72 h); OR
Pentobarbital 5 mg/kg IV load (give over 20 min); repeat as needed to produce burst-
suppression pattern on EEG. Complete EEG suppression may be needed if seizure activity persists during the bursts. Maintenance infusion 0.5–5 mg/kg/h. Monitor serum for lactate, osmolality, bicarb, and Cr for propylene glycol syndrome. 

Once burst-suppression pattern is established on EEG, defined by 10 s of suppression with 1–2 s bursts of cerebral activity, continue for 24–48 h. If the bursts contain epileptiform activity, consider complete EEG suppression. Monitor EEG every 1–2 h. Adjust medication dose as needed. 

Monitor for hypotension; ileus; propofol infusion syndrome; or propylene glycol syndrome (pentobarbital or IV lorazepam). 

Continue maintenance doses of phenytoin, levetiracetam, valproic acid, lacosamide, or phenobarbital; monitor and maintain therapeutic levels. 

Taper anesthetic medication at 24–48 h. If seizures recur, resume infusion for 24 h, then taper again. Continue this process as necessary. 

\[a\] Fosphenytoin dosing in PE.

AV, atrioventricular block; BP, blood pressure; BUN, blood urea nitrogen; CBC, complete blood cell; Cr, creatine; CPK, creatine phosphokinase; D50, dextrose 50%; EEG, electroencephalogram; Glu, glucose; IV, intravenous; NS, normal saline; PE, phenytoin equivalents.
Treatment of SE must proceed rapidly and deliberately. Table 151.3 outlines a management protocol. For generalized SE, the initial assessment and treatment should begin within 5 to 10 minutes of the onset of seizure activity. Dosing of drugs can be found in Tables 151.3 and 151.4, and pharmacologic properties and side effects in Table 151.4.

IV benzodiazepines are the appropriate initial treatment. The Veterans Affairs Status Epilepticus Cooperative Study Group trial suggested that phenobarbital is also effective as initial therapy, but phenytoin alone without a benzodiazepine may be less effective [24,27]. Diazepam and lorazepam are both effective in treating generalized SE [28], but lorazepam has a longer duration of action (2 to 24 hours), compared to diazepam (10 to 25 minutes) [29], and does not have extensive peripheral tissue uptake, unlike diazepam. Although lorazepam has slower CNS penetration than diazepam, the onset of action of less than 3 minutes is acceptable. For these reasons, lorazepam is the recommended first-line agent for SE. Both these drugs have significant and essentially the same cardiac, respiratory, and CNS depressant side effects [25]. Respiratory depression and apnea, which are potentiated by age and previous administration of sedative drugs, may occur abruptly with doses as small as 1 mg. Hypotension, which occasionally occurs, may be partially caused by the propylene glycol solvent contained in the IV forms of diazepam and lorazepam.

In 2012, the RAMPART study showed that if IV access was not available, intramuscular midazolam was as effective as IV lorazepam for the prehospital treatment of SE by paramedics, and this was not associated with an increase in respiratory compromise or seizure recurrence [30]. Early administration of adequate doses of IV lorazepam remains the preferred first-line treatment for SE in the emergency room and other controlled clinical environments. Rectal diazepam (0.2mg per kg) has been successful in achieving rapid therapeutic levels and effectively terminating prolonged generalized seizures [31]. Significant respiratory depression from rectal diazepam has not been reported [32]. IM administration of diazepam is unsuitable for the treatment of status owing to delayed peak levels [33]. Furthermore, the peak concentration after IM injection is much less than that after IV injection.

Phenytoin is usually given with benzodiazepines to control the SE and prevent recurrent seizures. A 20 mg per kg load is recommended, given at 50 mg per minute. If seizures continue, additional doses of up to another 10 mg per kg can be given. The serum level of phenytoin should be 15 to 30 mcg per mL. IM administration should not be used because it
results in precipitation at the injection site and has slow, erratic absorption. Hypotension, electrocardiographic changes, and respiratory depression can occur and may be due partly to the propylene glycol diluent [2]. Simultaneous cardiac monitoring should be performed, and slower infusion rates (25 mg per minute) should be considered in patients who are elderly owing to increased susceptibility to cardiopulmonary adverse effects [34]. Intravenous infusion of phenytoin carries a risk of medication extravasation into adjacent tissue. Tissue necrosis can rarely occur [35].

Fosphenytoin, a water-soluble prodrug of phenytoin, is rapidly converted enzymatically to phenytoin. Rapid and complete absorption occurs after IM administration [36,37]. Therapeutic phenytoin concentrations are attained in most patients within 10 minutes of rapid IV infusion (150 mg per minute) and within 30 minutes of slower IV infusion or IM injection [36,37]. Dosing for fosphenytoin is the same as for phenytoin, but needs to be given in “phenytoin equivalents.” Cardiac monitoring is required during IV infusions of fosphenytoin. Maintenance doses of phenytoin or fosphenytoin should be started within 24 hours of the loading dose, with levels maintained in the high therapeutic range (15 to 25 mcg per mL).

If there is contraindication to phenytoin or if seizures persist, levetiracetam, valproate sodium, phenobarbital, or lacosamide may be used instead as second line treatment of SE (See Table 151.3) [2,38–40]. Intravenous valproate is well tolerated, with few adverse effects [41–46]. Valproate levels should be monitored. With phenobarbital infusions, respiratory depression can occur, especially if benzodiazepines have been used.

SE persisting after this time is considered refractory SE (RSE). Treatment from this point on may vary. For drug-induced coma, all patients must be intubated. Agents commonly used for RSE include midazolam, propofol, or pentobarbital (see Table 151.3) [2,34]. All are extremely effective for suppressing clinical and electrographic seizures. Simultaneous EEG monitoring is mandatory during induction of coma. Phenobarbital is not used for this purpose, because it can result in very prolonged coma.

Propofol, a GABA agonist, is a potent antiepileptic agent [2,47,48].
Propofol has the advantage of rapid induction and elimination, but slow downward titration is important to avoid recurrent seizures [49]. One significant disadvantage of this drug is the propofol infusion syndrome. This consists of profound hypotension, rhabdomyolysis, hyperlipidemia, cardiac arrhythmias, and metabolic acidosis.

**Midazolam** is comparably well tolerated and effective. Compared to pentobarbital, patients on midazolam have less cardiac depression and regain consciousness more rapidly after discontinuation [50,51]. Midazolam can be used in combination with propofol to decrease risk propofol infusion syndrome. Tolerance to the antiepileptic effects of midazolam can develop after 36 to 48 hours, which can lead to escalating dose requirements. Because of this, if SE is not terminated within 72 hours of midazolam treatment, changing to an alternative infusion such as propofol or pentobarbital is recommended.

**Pentobarbital** infusion may result in cardiac depression, and careful hemodynamic monitoring is required. Vasopressors are frequently needed, and ileus is also common. Propylene glycol toxicity has been reported in patients treated with barbiturate coma for refractory SE. These patients can develop hypotension and hepatic and renal failure. Treatment may include hemodialysis [52].

There is relatively little prospective data to suggest that propofol, midazolam, or pentobarbital are dramatically different in efficacy for SE. Several studies seem to indicate that patients treated with pentobarbital have fewer treatment failures and breakthrough seizures, but more frequent episodes of hypotension. There is no clear difference in mortality among the three agents [53].

The dose of propofol, midazolam or pentobarbital must be sufficient to terminate any seizure activity seen on the EEG. In many cases, the goal is to produce a burst-suppression EEG pattern, characterized by a flat background of at least 10 seconds punctuated by bursts of mixed-frequency activity lasting 1 to 2 seconds in duration. If the bursts contain electrographic seizure activity, the coma should be deepened, at times to virtual electrocerebral silence. During this time of drug-induced coma, it is essential to maintain high therapeutic levels of all antiepileptic medications to avoid recurrence of SE upon tapering of anesthetic agents. Phenobarbital may be used as a bridge if initial weaning off pentobarbital results in recurrence of seizures. Temporary supratherapeutic levels of phenobarbital (i.e., 40 to 60 mcg per mL) may be needed in this situation.

NCSE must be treated quickly, although additional trials of
antiepileptic medications are usually warranted prior to intubation and initiation of anesthetic agents. When needed, the medication doses are comparable to those used in generalized SE (see Table 151.3). Both diazepam and lorazepam are effective in treating absence SE; focal motor SE; and focal dyscognitive SE. The response to benzodiazepines may be helpful for confirming the diagnosis if it is in question. The patient should also be started on antiepileptic medication appropriate for long-term management, given as a loading dose if appropriate. Valproate is very effective for treatment of absence SE as well as levetiracetam. Phenytoin is often ineffective at treating absence SE. Focal motor SE responds to phenytoin and other standard agents including levetiracetam, although epilepsy partialis continua can be notoriously resistant to treatment.

The ketogenic diet is an emerging nonpharmacologic treatment of superrefractory SE. The high-fat and low-protein/carbohydrate diet is administered via nasogastric tube which subsequently induces a metabolic shift toward acidosis, resulting in ketonuria, which can be present within a few days of initiation of the diet. Successful treatment of superrefractory NCSE with the ketogenic diet has been described [54].
CONCLUSION

SE is a true medical emergency and needs to be treated promptly and definitively. For convulsive SE, immediate termination of ongoing seizure activity; determination of underlying etiology; and medical stabilization of patients are essential. Lorazepam IV and more recently midazolam IM are medications for immediate short-term cessation of SE. A number of newer AEDs have been shown to be effective for the treatment of SE. There have been significant advances in ICU monitoring and management, as well as for the earlier identification of NCSE states. Physicians should be familiar with effective treatment protocols for SE, because prompt and appropriate therapy is essential for reducing morbidity and mortality.

1. Lowenstein DH, Bleck T, MacDonald RL: It’s time to revise the definition of status epilepticus. *Epilepsia* 40:120, 1999.

Guillain–Barré syndrome (GBS) was described by Guillain, Barré, and Strohl in 1916 as an acute flaccid paralysis with areflexia and elevated spinal fluid protein without pleocytosis [1]. It is the most common cause of rapidly progressive weakness due to peripheral nerve involvement, with an annual incidence of 0.6 to 2.0 cases per 100,000 population [2]. For decades, GBS has been viewed as an acute inflammatory demyelinating polyradiculoneuropathy (AIDP) affecting nerve roots and cranial and peripheral nerves of unknown cause that occurs at all ages. In the past 20 years, the recognition of primary axonal forms of GBS has broadened the spectrum of GBS to include the demyelinating form (AIDP) and axonal forms—acute motor axonal neuropathy (AMAN) and acute motor sensory axonal neuropathy (AMSAN), as well as the Miller Fisher syndrome. AIDP is the most common subtype in developed countries, whereas axonal forms are more common in northern China. Because of the potential for the development of respiratory insufficiency and autonomic nervous system abnormalities [3], GBS is most appropriately recognized as a potential medical and neurologic emergency that typically requires intensive care, to treat and manage the potential complications of the illness [4].

DIAGNOSIS

Clinical Features in Acute Inflammatory Demyelinating Polyradiculoneuropathy

GBS often occurs 2 to 4 weeks after a flu-like or diarrheal illness caused by a variety of infectious agents [3], including cytomegalovirus; Epstein–Barr and herpes simplex viruses; mycoplasma; Chlamydia; and Campylobacter jejuni [5]. It can also be an early manifestation of human immunodeficiency virus (HIV) infection before the development of an
immunosuppressed state [6]. Lyme disease may rarely produce a syndrome of polyradiculopathy reminiscent of GBS [7]. Other antecedent events include immunization; general surgery and renal transplantation; Hodgkin’s disease; and systemic lupus erythematosus [2,3].

The illness is heralded by the presence of dysesthesias of the feet or hands, or both. The major feature is weakness that evolves rapidly (usually over days) and classically has been described as ascending from legs to arms and, in severe cases, to respiratory and bulbar muscles. Weakness may, however, start in the cranial nerves or arms and descend to the legs or start simultaneously in the arms and legs [2]. Proximal muscles are often involved early in the course of the disease. Approximately 50% of patients reach the nadir of their clinical course by 2 weeks into the illness, 80% by 3 weeks, and 90% by 1 month [8]. Progression of symptoms beyond 4 weeks but arresting within 8 weeks has been termed subacute inflammatory demyelinating polyneuropathy (SIDP) [9], whereas progression beyond 2 months is designated chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), a disorder with a natural history different from GBS [10]. Up to 16% of patients with CIDP may present acutely as GBS; those that continue to progress to CIDP more often have pronounced sensory signs, and are less likely to have facial weakness, autonomic involvement, a preceding infectious illness, or require mechanical ventilation [11]. A small percentage of patients (up to 6%) have recurrent GBS; these patients are often younger than 30 years, have milder symptoms, and more often have Miller Fisher syndrome. Several years often pass between episodes, differentiating them from patients with treatment-related fluctuation, where worsening occurs within the first 8 weeks of disease onset after initial improvement/stabilization [12].

The extent and distribution of weakness in GBS are variable. Within a few days, a patient may become quadriparetic and become respirator dependent, or the illness may take a benign course and after progression for 3 weeks produce only mild weakness of the face and limbs.

**Physical Findings**

In a typical case of moderate severity, the physical examination discloses symmetric weakness in proximal and distal muscle groups with attenuation or loss of deep tendon reflexes (Table 152.1). In the early stage of the illness, there is no muscle wasting or fasciculation. If the attack is particularly severe and axons are interrupted, muscles undergo atrophy and scattered fasciculations may be seen after a number of months. Sensory loss is usually mild, although a variant of GBS is described in which sensory loss (involving large fiber modalities) is widespread, symmetric, and profound [8]. Respiratory muscles are often
involved, and 10% to 25% of patients require ventilator assistance [13] within 18 days (mean of 10 days) after onset [14].

AIDP, acute inflammatory demyelinating polyradiculoneuropathy; AMAN, acute motor axonal neuropathy; GBS, Guillain–Barré syndrome.

There is often mild to moderate bilateral facial weakness. Mild weakness of the tongue and the muscles of deglutition may also develop. Ophthalmoparesis from extraocular motor nerve involvement is unusual in the typical patient with GBS. In the Miller Fisher variant [15], however, ophthalmoplegia occurs in combination with ataxia and areflexia, with little limb weakness. Pupillary abnormalities have been noted in GBS [16] and in the Miller Fisher variant [17]. Papilledema is rare [18].

Autonomic nervous system disturbances occur in 50% of patients and are potentially lethal [3,4]. Autonomic dysfunction takes the form of excessive or inadequate activity of the sympathetic or parasympathetic
nervous system, or both [19]. Common findings include cardiac 
arrhythmias (e.g., persistent sinus tachycardia, bradycardia, ventricular 
tachycardia, atrial flutter, atrial fibrillation, and asystole); orthostatic 
hypotension; and transient or persistent hypertension. Other changes 
include transient bladder paralysis; increased or decreased sweating; and 
paralytic ileus. The pathophysiology of these changes is not completely 
understood but may be caused by inflammation of the thinly myelinated 
and unmyelinated axons of the peripheral autonomic nervous system. A 
neuropathy predominantly affecting the peripheral autonomic nervous 
system has been described that may have a pathogenesis similar to that of 
GBS [20].

Clinical Features in Axonal Forms

Like AIDP, axonal forms present with rapidly progressive weakness, 
areflexia, and albuminocytological dissociation but differ in the following 
ways: (1) Patients with AMAN lack sensory abnormalities; (2) most often 
children and young adults in northern China, Mexico, or Japan develop 
AMAN during summer months; (3) Many have experienced an 
antecedent Campylobacter jejuni infection. Patients with AMAN also 
have a more rapid progression to their nadir, but recovery times are 
quicker [21] or similar [22] to AIDP in some, whereas other patients have 
a protracted recovery [21].

AMSAN is characterized by sensory and motor deficits, and a long time 
to recovery. In the series by Feasby et al. [23], these patients had a much 
shorter time to peak severity (1 week), had more severe symptoms with 
more than half requiring mechanical ventilation, and had inexcitable 
motor nerves; and most had a poor recovery.

Laboratory Features

The most characteristic laboratory features of GBS are an abnormal 
cerebrospinal fluid (CSF) profile with albuminocytologic dissociation 
(elevated protein without pleocytosis) and abnormal nerve conduction 
studies.

CSF examination is helpful in supporting the diagnosis of GBS. 
Although the CSF profile is usually normal during the first 48 hours after 
onset [8], by 1 week into the illness, the CSF protein is elevated in most 
patients, sometimes to levels as high as 1 g per dL. Rarely, even several 
weeks after onset of GBS, the CSF protein remains normal and the 
diagnosis must rest on the presence of otherwise typical clinical features 
[8]. The cell count may be slightly increased but rarely exceeds 10 cells 
per µL; the cells are mononuclear in nature. When GBS occurs as a 
manifestation of HIV infection or Lyme disease, the CSF white cell count 
is generally increased (25 to 50 cells per µL). The CSF glucose is expected
Electrodiagnostic studies in AIDP typically show a non-length dependent, motor and sensory demyelinating polyneuropathy with slowing of motor nerve conduction velocities (less than 70% of the lower limit of normal); increases in distal motor latencies; and evidence of temporal dispersion and partial conduction block along motor fibers. F-waves are absent or have prolonged latencies; and sensory responses are reduced or absent [8,24]. The amplitude of the evoked motor responses may be reduced because of axon loss or distal nerve conduction block, and the responses are frequently dispersed because of differential slowing along still-conducting axons [8,24]. Because the pathologic process may be restricted to spinal nerve roots and proximal nerve segments, routine nerve conduction studies early in the course of the neuropathy may be normal initially. In such cases H-reflexes are often absent and F-responses are abnormal (absent or prolonged in latency). These abnormal late responses along with sural sparing (normal sural response), and reduced or absent median sensory response is characteristic of early GBS [25]. Early in the course of GBS, needle electrode examination of voluntary contraction of weak muscles demonstrates reduced motor unit potential recruitment (decreased numbers of normal appearing motor unit potentials firing rapidly) because of nerve conduction block. Several weeks later, needle examination of weak muscles reveals active denervation changes, with fibrillation potentials and positive sharp waves, reflecting the motor axon loss that is often part of AIDP, and central to the pathogenesis of AMAN and AMSAN.

In patients with the severe axonal form of GBS, AMSAN, motor and sensory nerves may be electrically inexcitable [23]. In AMAN, motor responses are low or absent, whereas conduction velocities and sensory responses are normal [26]. The electrodiagnostic findings in the Miller Fisher syndrome are indicative of a sensory neuronopathy with reduced or absent sensory responses throughout despite normal motor studies.

Except for a mild increase in the erythrocyte sedimentation rate, hematologic studies are normal. Serum electrolytes may disclose hyponatremia [3], sometimes to a marked degree, because of inappropriate secretion of antidiuretic hormone (SIADH) caused by a disturbance of peripheral volume receptors. There may be evidence of previous viral or *mycoplasma* infection, such as lymphopenia or atypical lymphocytes. In some cases, evidence of recent viral infection may be sought by measuring antibody (immunoglobulin [Ig] M) titers against specific infectious agents, especially cytomegalovirus, Epstein–Barr virus, and *C. jejuni*. In selected cases, screening for HIV infection should be undertaken.

Approximately 90% of Miller Fisher syndrome patients have high titers of GQ1b antibodies, and their presence confirms the diagnosis of this
disorder. Antibodies to GM1, GD1a, GM1b, and GalNac-GD1a are associated with axonal forms of GBS. Anti-GM1 antibodies are reported in 10% to 42% of AMAN patients [27].
DIFFERENTIAL DIAGNOSIS

A number of well-defined conditions cause an acute or subacute onset of generalized weakness and must be differentiated from GBS (Table 152.2). These are disorders of the motor unit affecting the neuromuscular junction (e.g., myasthenia gravis and botulism); peripheral nerve (e.g., tick paralysis, shellfish poisoning, toxic neuropathy, acute intermittent porphyria, and diphtheritic neuropathy); motor neuron (e.g., amyotrophic lateral sclerosis, poliomyelitis, and West Nile virus [WNV] neuroinvasive disease); and muscle (e.g., periodic paralysis, metabolic myopathies, and inflammatory myopathies). Other conditions characterized by severe generalized weakness are defined by the setting in which they are encountered—the intensive care unit (ICU)—and are designated critical illness polyneuropathy and the myopathy of intensive care.

Shellfish poisoning

Rapid onset (face, finger, and toe numbness)
Follows consumption of mussels/clams

Toxic neuropathies

EMG: usually axon loss

Organophosphorus

Acute cholinergic reaction toxicity

Porphyric neuropathy

Mental disturbance
Abdominal pain

Diphtheritic neuropathy

Prior pharyngitis
Slower evolution
Palatal/accommodation paralysis
Myocarditis

Poliomyelitis

Weakness, pain, and tenderness
Preserved sensation
Cerebrospinal fluid: protein and cell count elevated

West Nile virus neuroinvasive disease

Associated fever, meningitis, or encephalitis
Asymmetric weakness
Cerebrospinal fluid: protein and cell count elevated

Periodic paralysis

Reflexes normal
Cranial nerves and respiration spared
Abnormal serum potassium concentration

Critical illness neuropathy

Sepsis and multiorgan failure >2 wk
EMG: axon loss

Acute myopathy of intensive care

Tetraparesis and areflexia
Follows prolonged treatment with neuromuscular-blocking agent and
corticosteroids
Trauma, status asthmaticus, and organ transplantation associated

Clinical and EMG features of myopathy

EMG, electromyogram.

Intensive Care Unit–Related Weakness

Unlike neuromuscular emergencies such as GBS, myasthenia gravis, or porphyria, in which rapidly progressive weakness develops before admission to the ICU, a number of conditions (polyneuropathy, myopathy, and neuromuscular junction disease) affect patients already in the ICU because of severe systemic illnesses. These conditions are discussed in more detail in Chapter 154. Critical illness polyneuropathy is an axonal sensory and motor polyneuropathy characterized by difficulty weaning from the ventilator, distal greater than proximal muscle weakness, and reduced or absent reflexes that develop in patients with sepsis and multiorgan failure [28]. The development of weakness in the midst of critical illness, as seen in critical illness polyneuropathy, helps differentiate this disorder from axonal GBS, in which weakness develops days to weeks after an infection [29]. A severe necrotizing myopathy can also be seen in critically ill patients [30]. An acute myopathy of intensive care initially described in patients treated with a combination of high-dose corticosteroids (equal to or greater than 1,000 mg methylprednisolone) and neuromuscular blocking agents (NMBAs) for status asthmaticus [31] may also be encountered in the setting of trauma, organ transplantation, burns, and critical illness. Patients have variable degrees of generalized weakness, including respiratory muscles, and this is often recognized when a patient has difficulty weaning from the ventilator. Prolonged neuromuscular blockade after use of the nondepolarizing NMBAs can be seen especially in patients with coexistent renal failure and metabolic acidosis. Presumably, the presence of an active metabolite accounts for the prolonged weakness [32].

Disorders of the Neuromuscular Junction

In patients with myasthenia gravis, limb weakness is predominant proximally and almost always associated with ocular and sometimes pharyngeal muscle weakness (see Table 152.2; see Chapter 153). Muscular fatigability is a hallmark of the disease. Botulism may also
cause acute weakness 6 to 36 hours after ingestion of the toxin formed by *Clostridium botulinum*. The condition is characterized by weakness of cranial nerve–innervated muscles, autonomic abnormalities (unreactive pupils and ileus), and occasional respiratory muscle weakness necessitating ventilator assistance. Electrodiagnostic findings of low compound motor action potential amplitudes with post-exercise facilitation are key in diagnosing this condition.

**Disorders of Peripheral Nerve**

*Tick paralysis* is produced by a toxin contained in the head of the tick *Dermacentor andersoni* or *D. vanabilis* that blocks nerve conduction in the fine terminal portions of motor and sensory nerves. Weakness associated with sensory impairment develops rapidly after the tick has embedded itself into the victim, usually over 1 to 2 days. *Shellfish poisoning* gives rise to symptoms immediately after contaminated mussels or clams are eaten. Patients complain of face, finger, and toe numbness and then note the development of rapidly progressive descending paralysis, which may involve respiratory muscles.

*Toxic neuropathies* may be caused by a number of heavy metals, including arsenic, thallium, and lead. These and other potential neurotoxins (e.g., nitrofurantoin) and industrial agents (e.g., hexacarbons) may produce a rapidly evolving peripheral neuropathy. Most acute toxic neuropathies are axon loss in character, but in the case of arsenic poisoning, electrodiagnostic features may simulate a demyelinating process identical to some forms of GBS [33]. Organophosphorus insecticide toxicity causes a short-lived acute cholinergic phase marked by miosis, salivation, sweating, and fasciculation followed in 2 to 3 weeks by an acute axon-loss polyneuropathy [34]. An intermediate syndrome occurring 24 to 96 hours after the cholinergic phase and characterized by multiple cranial nerve palsies and respiratory failure has also been described [35]. The latter probably results from a defect at the neuromuscular junction.

*Acute intermittent porphyria* causes an acute polyneuropathy clinically similar to GBS but differing by its association with mental disturbance and abdominal pain. Attacks of paralysis are precipitated by ingestion of a variety of drugs, including alcohol, barbiturates, estrogens, phenytoin, and sulfonamides. The diagnosis may be established by demonstrating increased levels of porphobilinogen and δ-aminolevulinic acid in the urine.
Diphtheritic neuropathy occurs 2 to 8 weeks after a throat infection. During the height of the infection, there is numbness of the lips and paralysis of pharyngeal and laryngeal muscles. At the time of the neuropathy, diphtheria organisms may be cultured from the throat. Other clues to the diagnosis are clinical and electrocardiographic features of myocarditis.

Disorders of Motor Neurons

Amyotrophic lateral sclerosis is a chronic disorder of the motor system that generally evolves over several years to produce a state of severe generalized muscle weakness, atrophy, and fasciculations. In most instances, respiratory muscle weakness occurs in the latter stages of the illness after the diagnosis has been established. Rarely, however, patients present with acute to subacute respiratory muscle weakness (ventilatory failure) as the first clinical manifestation of this disease. The examination of such patients often discloses some features of lower motor neuron loss (muscle atrophy and fasciculations) in limb and bulbar muscles. The presence of brisk deep tendon reflexes and preserved sensation helps to distinguish this disorder from the neuropathies that might cause acute ventilatory failure. Unlike the situation in GBS where a picture of albuminocytologic dissociation is found, the CSF findings in amyotrophic lateral sclerosis are normal.

Poliomyelitis is rarely seen today, but it has developed in close contacts of newborns immunized with the live attenuated oral vaccine, and individuals whose own immunity to the virus has become inadequate. The disease is characterized by weakness of rapid onset along with severe muscle pain and tenderness. Respiratory muscles are often involved. Deep tendon reflexes are depressed. The illness is distinguished from GBS clinically by the preservation of sensation and the CSF findings. Serum antibody studies may help identify the illness.

A poliomyelitis-like syndrome may also be seen with WNV neuroinvasive disease. Infection of the anterior horn cells by the WNV produces an acute flaccid paralysis, with asymmetric weakness of one or more limbs, particularly the legs, along with hyporeflexia or areflexia. Overt sensory loss is typically absent, whereas loss of bowel and bladder function may occur. Unlike GBS, there may be an associated meningitis, encephalitis, or fever, in addition to CSF pleocytosis and elevated CSF protein. Diagnosis depends on detection of WNV-specific antibodies in serum or CSF [36].

Disorders of Muscles

Periodic paralysis (hyperkalemic or hypokalemic) is a disorder of muscle usually inherited in an autosomal-dominant fashion. Patients develop
generalized weakness over a period of hours (see Table 152.2). Cranial nerve–supplied muscles are spared, there is generally no respiratory muscle involvement, reflexes are normal, and there is no sensory involvement. Serum potassium measurements aid in the diagnosis.

Rarely, metabolic myopathies may present with the sudden onset of muscle weakness. Patients with abnormalities of glycogen metabolism (e.g., phosphorylase deficiency) or lipid metabolism (e.g., carnitine palmityl transferase deficiency) may develop weakness associated with severe cramps and muscle fiber necrosis; the latter may result in creatine kinase elevations and myoglobinuria.

*Dermatomyositis*, an inflammatory myopathy, may present with the acute onset of proximal muscle (and, rarely, respiratory muscle) weakness. In contrast to the acute polyneuropathies, deep tendon reflexes are spared, cranial nerves are rarely involved, and serum creatine kinase is elevated.
PATHOGENESIS

AIDP is caused by immunologically mediated demyelination of the peripheral nervous system [3]. It is likely that humoral and cellular components of the immune system participate in macrophage-induced peripheral nerve demyelination [2,37]. Although the histological appearance of AIDP resembles experimental autoimmune neuritis, in which a predominantly T-cell–mediated immune response is directed against peripheral nerve myelin proteins, the role of T-cell–mediated immunity in AIDP remains unclear [37]. The finding of complement activation markers along the outer surface of the Schwann cell [38] have led to the speculation that complement-fixing antibodies directed toward as yet unidentified epitopes on the outer surface of the Schwann cell play a role in AIDP. Axonal degeneration may occur, especially in severe cases, as a “bystander” when there is intense inflammation [39,40].

In axonal subtypes, the immune response is targeted to a different portion of the peripheral nerve, the axon [41]. There is strong evidence that antibodies directed against ganglioside antigens on the axolemma target macrophages to invade the axon at the node of Ranvier [37]. The rapid decline and subsequent quick recovery in many AMAN patients suggests that severe axonal degeneration of the nerve roots is unlikely to be the pathological basis for this disorder; proposed mechanisms include physiological block of conduction or very distal degeneration and subsequent regeneration of the intramuscular motor nerve terminals [22].

The presence of antiganglioside antibodies (GM1, GD1a, GM1b, and GalNAcGD1a antibodies in axonal GBS and GQ1b in Miller Fisher syndrome), and the finding of ganglioside-like epitopes on some strains of C. jejuni have led to the concept of molecular mimicry [42], in which an immune attack occurs on the epitope shared by the nerve fiber and infectious organism [43], as a possible mechanism for GBS, especially C. jejuni–associated GBS. There is increasing evidence that anti-GM1 antibodies block sodium ion channels at the nodes of Ranvier, transiently producing conduction failure [27]. In addition, Koga et al. [44] found evidence that the genetic polymorphism of C. jejuni determines the production of specific autoantibodies and correlates with the clinical presentation of GBS, possibly through modification of the host-mimicking molecule.
PATHOLOGY

Pathological studies of nerves from patients dying with GBS have usually shown infiltration of the endoneurium by mononuclear cells, with a predilection for a perivenular distribution [39]. The inflammatory process occurs throughout the length of the nerve, from its origin at a root level to the distal ramifications of nerve twigs in the substance of muscle fibers. The brunt of the inflammatory process, however, occurs at more proximal levels (e.g., roots, spinal nerves, and major plexuses) and takes the form of discrete foci of inflammation. Macrophages invade intact myelin sheaths and denude the axons [37]. Patients with prominent axon loss are least likely to recover fully and may be left with functionally significant residual motor weakness.

In AMAN and AMSAN, there is evidence of Wallerian-like degeneration of nerve fibers, but only minimal inflammation or demyelination. Macrophages are seen within the periaxonal space especially at the nodes of Ranvier, displacing or surrounding the axon, and leaving the myelin sheath intact [26]. Abnormalities are seen in nerve roots and peripheral nerves; in those with AMSAN, motor and sensory fibers are affected, whereas only motor fibers are affected in AMAN, with sparing of sensory fibers.
NATURAL HISTORY

The natural history of GBS in the moderately to severely affected patient (i.e., a patient who is unable to walk or who has severe respiratory muscle weakness requiring a ventilator) is usually one of gradual improvement. The ability to walk unassisted returns, on average, in approximately 3 months; in the subset of respirator-dependent patients, the average time to recovery is 6 months [45].
The three major treatment issues in GBS are controlling respiration and deciding when to intubate the patient, recognizing and managing autonomic dysfunction, and determining which patients are candidates for plasmapheresis or intravenous immunoglobulin (IVIG) (Table 152.3).

**Treatment:**

| Plasmapheresis | Exchange a total of 200 mL plasma/kg body weight over 7–14 d (40–50 mL/kg for 3–5 sessions) |

---

\(^a\)
Albumin is used as replacement solution, not fresh-frozen plasma. During plasmapheresis, monitor blood pressure and pulse every 30 min.

Obtain complete blood cell count (baseline and before each exchange to calculate plasma volume).

Obtain immunoglobulin levels before first exchange and after last exchange; if immunoglobulin G <200 mg/dL after last plasma exchange, infuse 400 mg/kg IVIG.

**IVIG**

| 2 g/kg divided over 5 consecutive d<sup>b</sup> (0.4 g/kg/d for 5 d) |

This is the authors’ approach, following the Guillain–Barré Syndrome Study Group guidelines [44]. Other published guidelines recommend two sessions (exchanging 40 mL/kg per session) for ambulatory patients and four sessions (exchanging 40 mL/kg per session) for nonambulatory patients [53].

The authors adhere to the protocol published by the Dutch Guillain–Barré Study Group [54].

IVIG, intravenous immunoglobulin; VC, vital capacity.

Patients with GBS require excellent nursing care, medical management, and emotional support. Respiratory failure is one of the most serious complications of GBS. Need for a ventilator cannot be reliably predicted on the basis of extent of weakness; however, patients who are highly likely to require mechanical ventilation are those with rapid disease progression, bulbar weakness, autonomic dysfunction, and bilateral facial weakness [46]. Patients must be followed up carefully with measurements of maximum inspiratory pressure and forced vital capacity (FVC) (Fig. 152.1) until weakness has stopped progressing, so the respiratory insufficiency can be anticipated and managed appropriately. A normal FVC is 65 mL per kg; a level of 30 mL per kg is generally associated with a poor forced cough and requires careful observation and management with supplemental oxygen and chest physical therapy. At 25
mL per kg, the sigh mechanism is compromised and atelectasis occurs, leading to hypoxemia. Ropper and Kehne [47] suggest intubation if any one of the following criteria is met: mechanical ventilatory failure with reduced expiratory vital capacity (VC) of 12 to 15 mL per kg; oropharyngeal paresis with aspiration; falling VC over 4 to 6 hours; or clinical signs of respiratory fatigue at a VC of 15 mL per kg. Lawn et al. [46] found the following respiratory factors to be highly associated with progression to respiratory failure: VC less than 20 mL per kg; maximal inspiratory pressure (MIP) less than 30 cm H$_2$O; maximal expiratory pressure (MEP) less than 40 cm H$_2$O; or a reduction of more than 30% of VC, MIP, or MEP in 24 hours. Elective intubation may be considered in these patients at particularly high risk for progression to respiratory failure. Intubation should be accomplished with a soft-cuff low-pressure endotracheal tube. A decision to delay tracheostomy for 7 to 10 days is likely to avoid the operation in as many as one-third of patients who improve rapidly and can be extubated after the first few days [47]. Complications of intubation and ventilator assistance are described in Chapters 8 and 166.

The nursing and medical team must also be aware of the many autonomic nervous system disturbances that can occur [19]. Fluctuating blood pressure with transient hypertensive episodes, sometimes
associated with extreme degrees of agitation, may be present. Other manifestations of sympathetic nervous system overactivity include sudden diaphoresis, general vasoconstriction, and sinus tachycardia. Evidence of underactivity of the sympathetic nervous system includes presence of marked postural hypotension and heightened sensitivity to dehydration and sedative–hypnotic agents. Excessive parasympathetic nervous system activity is reflected in facial flushing associated with a feeling of generalized warmth and bradycardia. Electrocardiographic changes, consisting of ST-and T-wave changes, also occur. Therefore, careful monitoring of blood pressure, fluid status, and cardiac rhythm is absolutely essential to manage the GBS patient. Hypertension may be managed with short-acting \( \alpha \)-adrenergic blocking agents, hypotension with fluids, and bradyarrhythmias with atropine [19]. As noted earlier, hyponatremia may occur and is probably best managed by free water restriction.

The bedridden patient needs to be turned frequently to avoid the development of pressure sores. Paralyzed limbs require the attention of the physiotherapist so that passive limb movements can be carried out and contractures prevented. The ICU team needs to be aware of the potential for development of compression neuropathies (most commonly of the ulnar and peroneal nerves), and insulating pads should be placed over the usual susceptible sites (the elbow and the head of the fibula). Pain may be treated with standard doses of analgesic agents, but they do not often provide adequate relief. Gabapentin or carbamazepine is particularly helpful in treating the pain in the acute phase [48] and, when disabling, epidural morphine may be necessary [49]. Deep venous thrombosis and pulmonary embolism are ever-present dangers in the bedridden patient with immobilized limbs; for these patients, in addition to physical therapy, subcutaneous heparin (5,000 U twice per day) and support stockings are recommended [48].

A number of multicenter studies [45,50,51] showed that plasmapheresis has a beneficial effect on the course of the illness, even in those patients with several poor prognostic signs [52]. Patients treated with plasmapheresis are able to walk, on average, 1 month earlier than untreated patients; respirator-dependent patients so treated walk 3 months sooner than those who do not receive plasma exchange [45]. The GBS study group guidelines recommend exchanging 200 to 250 mL plasma per kg body weight over 7 to 14 days in three to five treatments [45]. Five percent salt-poor albumin is used as replacement fluid (fresh-frozen plasma should be avoided because of risks of hepatitis, HIV, and
occasionally pulmonary edema). It is important to keep in mind, however, that there are also risks with albumin, including bleeding, thrombosis, and infection (owing to loss of coagulating factors and γ-globulins during plasma exchange, which are not present in the albumin replacement fluid). After each exchange, γ-globulin can be infused to prevent infection.

Plasmapheresis, in general, is recommended for patients who have reached or are approaching the inability to walk unaided, who require intubation or demonstrate a falling VC, and who have weakness of the bulbar musculature leading to dysphagia and aspiration [53]. The French Cooperative Group on Plasma Exchange in Guillain–Barré Syndrome [54] also showed that treatment of patients with mild GBS (i.e., those who are still ambulatory) is beneficial; two plasma exchanges were more beneficial than none in time to onset of motor recovery in patients with mild GBS. Patients with moderate (not ambulatory) or severe (mechanically ventilated) GBS benefited from four exchanges; those with severe GBS did not benefit any further with the addition of two more exchanges. Because of its potential for inducing hypotension, patients who have compromise of their cardiovascular system or autonomic dysfunction may not tolerate this procedure. Plasmapheresis is safe in pregnant women and children [4]. Plasmapheresis is generally not used in patients who are no longer progressing 21 days or more after the onset of GBS.

For many years, plasmapheresis was the gold standard for the treatment of GBS. In 1992, a large randomized trial performed by Dutch investigators demonstrated that treatment with IVIG was at least as effective as plasmapheresis and might be superior [55]. A subsequent large randomized controlled trial (the Plasma Exchange/Sandoglobulin Guillain–Barré Syndrome Trial Group) confirmed the equivalence of IVIG and plasma exchange; in addition, there was no substantial benefit of using a combination of plasma exchange followed by IVIG [56]. In light of these studies, plasma exchange or IVIG may be used to treat GBS. Although both treatments are equally efficacious, IVIG has become the preferred treatment because of its relative ease of administration (plasmapheresis is not available in all centers, and it requires good venous access and a stable cardiovascular system). In 3% to 12% of patients given IVIG, side effects may occur that range from minor reactions such as flulike symptoms, headache, nausea, and malaise to more severe side effects, including anaphylactic reactions in IgA-deficient persons, transmission of hepatitis C, aseptic meningitis, and acute renal failure in those with renal insufficiency. Absolute contraindications to IVIG are unusual, however. For example, patients with IgA deficiency may be given an IgA-poor preparation with very careful monitoring and precautions (pretreatment with corticosteroids, diphenhydramine, and
acetaminophen); individuals with renal insufficiency must be given an IVIG sucrose-poor preparation with very close monitoring of their renal status and consultation with a specialist in Nephrology before infusion.

A recent American Academy of Neurology practice parameter recommends treatment of GBS patients who are unable to walk with either plasmapheresis or IVIG; treatment is beneficial if given within 4 weeks of onset of neuropathic symptoms for plasmapheresis and within 2 weeks (and possibly 4 weeks) of onset for IVIG [57]. For those patients who are still ambulatory, plasmapheresis may also be considered if given within 2 weeks of onset. Treatment with plasmapheresis followed by IVIG is not recommended.

In a small number of patients (5%), spontaneous relapse occurs within days to weeks after treatment with IVIG or plasmapheresis, often in those treated early in their illness. Relapse rates are similar in frequency between IVIG and plasmapheresis [58]. Although retreatment with the same therapy is commonly practiced [59], evidence-based literature is lacking regarding the efficacy of repeat treatment [58]. Retreatment with the same therapy has also been suggested in those patients who are severely affected and unresponsive to treatment.

Although it seems intuitively obvious that treatment of GBS with corticosteroids should be beneficial, corticosteroids are ineffective and are not recommended in the treatment of GBS.

Finally, it is most important to address the emotional needs of the patient with GBS, who will almost certainly be anxious, fearful, and depressed. The strong likelihood of a good outcome, even in ventilated patients, is noted later in this chapter. Sometimes, it is helpful for the patient to speak with a person who has recovered from GBS.
OUTCOME AND PROGNOSTIC FACTORS

In most patients recovery occurs over weeks or months, but in some patients, muscle strength may take 1.5 to 2.0 years to reach its best state with an intensive rehabilitation program [2]. Recovery is not always complete; only 60% of patients recover full motor strength at 1 year, whereas 14% have severe motor problems. About 80% are able to walk independently at 6 months, improving to 84% by 1 year [60]. Although patients who are restored to nearly normal function can resume work and leisure activities, some degree of ankle dorsiflexor weakness or numbness of the feet is commonly encountered. About 5% to 10% have a protracted course, are ventilator dependent for several months, and do not fully recover [61]. Despite close monitoring in the ICU, deaths from GBS do occur, with mortality in the range of 3% to 8% [4]. Causes of fatal outcomes include dysautonomia, sepsis, acute respiratory distress syndrome, and pulmonary emboli [4].

Poor prognostic factors include older age (≥50 years); severe disease at nadir (bedbound or requiring mechanical ventilation); rapid onset of disease; preceding diarrheal illness; and evidence of axonal loss (reflected on electrodiagnostic studies) [27,37,60,62]. More recently, elevated CSF neurofilament levels predicted poor outcome, presumably reflecting axonal damage of the proximal motor nerve root [63]. A clinical prognostic scoring system has been developed to help predict the risk of respiratory failure during the first week along with the risk of being unable to walk at 6 months using several of the above prognostic factors [64,65]; it is available online at https://gbstools.erasmusmc.nl/prognosis-tool.
SUMMARY

Careful attention to the patient’s history and thorough examination usually point to the diagnosis of GBS, which may be corroborated by the CSF findings (i.e., albuminocytologic dissociation) and results of electrophysiologic testing (i.e., acquired demyelinating or axon-loss polyneuropathy). The mainstay of treatment is excellent nursing and medical care, with close attention to respiratory and autonomic function. Although 10% of patients with GBS are left with substantial residual neurologic deficits, the majority improve and resume their premorbid lifestyles; plasmapheresis and IVIG have been shown to enhance recovery.

Advances in the management of GBS, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 152.4.

Chapter 153

Myasthenia Gravis in the Intensive Care Unit

ISABELITA R. BELLA • JOHNNY S. SALAMEH

Few physicians have more than a passing acquaintance with myasthenia gravis, although it is by no means rare. The key to handling the emergent problems associated with myasthenia is simply the management of airway and ventilatory support with the same care as in any other instance of respiratory failure (see Chapters 8, 65, and 166). With respiration under control, the treatment of the underlying disease can be unhurried and orderly, and it is successful in most patients. This chapter reviews briefly the pathogenesis, clinical spectrum, and diagnosis of myasthenia gravis and focuses on the intensive care setting, including management of the patient in crisis or in the perioperative period.

PATHOGENESIS

Myasthenia gravis is an autoimmune disorder of neuromuscular transmission [1]. Circulating antibodies react with components of acetylcholine receptors (AChRs) within postsynaptic muscle membrane and activate complement-mediated lysis of the muscle membrane, accelerate receptor degradation, and impair receptor activation (i.e., interfere with normal receptor activation by acetylcholine) [2]. The result is fewer receptors that can be activated at affected neuromuscular junctions, causing weaker muscular contraction. Electrophysiologic study of myasthenic neuromuscular junctions discloses end-plate potentials that are diminished in amplitude [3]. These observations have been clearly linked to the receptor alterations and an altered postsynaptic response to normal quantal transmitter release from the presynaptic nerve terminals. Understanding of this underlying pathophysiology has, in turn, enabled rational approaches to treatment. Various immunosuppressive therapies and acetylcholinesterase inhibitors are
primary therapeutic options in managing myasthenia gravis (see later).
EPIDEMIOLOGY

Myasthenia gravis is not rare; its prevalence in Western populations is approximately 1 in 20,000 [4]. The overall female to male ratio is approximately 3:2, although there are two distinct sex-specific incidence peaks, with the incidence among women peaking in the third decade and that among men in the fifth to sixth decades. A mild familial predisposition has been noted, although Mendelian inheritance does not apply.
The clinical spectrum of myasthenia gravis is characterized as much by its diversity as it is by its common themes. It may range from a mild and relatively inconsequential disease over a normal lifetime to a fulminant incapacitating disorder. The course of a given patient may also vary widely. The clinical hallmarks of the disease are weakness and exaggerated muscle fatigue. The specific muscles involved and the severity of weakness are highly variable, between individuals and within the same individual over time.

Ocular muscles are most frequently involved; diplopia is common, and various patterns of ophthalmoparesis are seen. Bulbar muscles are also frequently affected, leading to varying combinations of facial paresis, dysarthria, and dysphagia. Ptosis is common, but the pupils are never affected. Limb muscle involvement may vary from very isolated weakness to generalized (usually proximal) weakness and fatigability. Respiratory muscle weakness is unfortunately not rare, and respiratory insufficiency and the inability to handle oral and upper airway secretions are the critical problems that bring myasthenics to the intensive care setting. Myasthenia should also be considered in any patient who cannot be weaned from ventilator support after an otherwise uncomplicated surgical procedure.

Approximately 15% to 20% of myasthenics have only ocular and eyelid involvement. Longitudinal studies indicate that if an individual manifests only oculomotor weakness for more than 2 years, there is little chance of later limb or respiratory weakness. Although several clinical classification schemes have been devised for categorizing myasthenics according to the distribution and severity of their disease, it is preferable to emphasize the fact that myasthenics often fluctuate over time, with variability rather than constancy being the norm. Some factors contributing to fluctuations of strength are recognizable (see later); many fluctuations appear to occur at random.
DIAGNOSTIC STUDIES

The diagnosis of myasthenia gravis is clinically suggested in patients who present with chronic ocular, bulbar, or appendicular weakness, variable over time, with preservation of normal sensation and reflexes. More restricted presentations require a much broader differential diagnosis. Myasthenia gravis should always be considered in the differential diagnosis of isolated ocular or bulbar weakness. Again, prominent muscular fatigability and temporal fluctuation are key features of the disease. Normal pupils, normal sensation, and normal reflexes are to be expected and are helpful in diagnosing myasthenia gravis when coincident with an acute or subacute paralytic illness.

Once the diagnosis of myasthenia gravis is suggested, confirmation rests on the exclusion of other diseases and supporting clinical and laboratory studies. It is important to stress that although abnormal tests may be diagnostic, normal test results do not exclude the diagnosis.

Edrophonium Test

Edrophonium hydrochloride (Enlon; formerly “Tensilon”) is a fast, short-acting parenteral cholinesterase inhibitor. It reaches peak effect within 1 minute after intravenous injection and persists to some extent for at least 10 minutes. Myasthenic weakness typically improves transiently after administration of 4 to 10 mg (0.4 to 1.0 mL). The edrophonium test may be blinded, with drug or normal saline being injected. Whether drug or placebo, a 0.2-mL test dose is given to screen for excessive cholinergic side effects, such as cardiac arrhythmia, gastrointestinal hyperactivity, or diaphoresis. A resuscitation cart should always be available, and patients with known cardiac disease and elderly patients warrant electrocardiographic monitoring. The remaining 0.8 mL is given after 1 minute. Interpretation of the test depends on identifying and observing an unequivocal baseline muscular deficit that can be improved following the injection of edrophonium. Ptosis and ophthalmoparesis, if present, are semiquantifiable and well suited; if respiratory compromise is present, monitoring maximum inspiratory pressure (MIP) or vital capacity is useful. As a general rule, positive responses are dramatic; if there is any doubt about the positivity of the test, it should be considered negative. False-positive edrophonium tests are quite rare; false negatives are common. In children, the appropriate test dose is 0.03 mg per kg, one-fifth of which may be given as a test dose.
Neostigmine is a longer-acting parenteral cholinesterase inhibitor that sometimes effects a more obvious clinical response. It is also typically associated with more obvious autonomic side effects. The 1.5-mg test dose (0.04 mg per kg in children) should therefore be preceded by 0.5 mg of atropine; both may be given subcutaneously.

**Serologic Testing**

Recognition of the immune nature of myasthenia gravis has provided a relatively sensitive and highly specific diagnostic study. Approximately 85% of myasthenics have detectable serum antibodies, which bind to AChRs [5]. The sensitivity drops to 70% in those with purely ocular myasthenia [6]. The antibodies themselves constitute a heterogeneous group, reacting against various receptor subunits. Although the actual antibody titer is of little significance, correlating poorly with the severity of disease or clinical response to therapy, the presence of antibodies is a strong indication of the disease. A normal test does not exclude the diagnosis, especially in the patient presenting with predominantly ocular symptoms and signs. Of note, these antibodies have also been found in a small percentage of patients with Lambert–Eaton myasthenic syndrome; patients with autoimmune liver disease; and patients with lung cancer without neurologic disease [6].

Among seronegative myasthenic patients, from 30% to 70% may be found to have antibodies directed against muscle-specific tyrosine kinase [MuSK], an enzyme that catalyzes AChR aggregation in the formation of neuromuscular junctions [7]. Animal models have also recently shown that MuSK antibodies may reduce AChR clustering and thus impair neuromuscular transmission [8]. Patients who have antibodies to MuSK are often young women (onset of symptoms before 40 years of age) with prominent bulbar involvement [9] and neck or respiratory muscle weakness [7]. They tend to have more severe disease requiring aggressive immunosuppressive treatment [9] and have a higher frequency of respiratory crisis compared to seronegative or AChR-positive myasthenics [10]. Unlike patients with antibodies to AChR, there appears to be a correlation between MuSK antibody levels and disease severity, with antibody levels often decreasing after various immunosuppressive treatments except thymectomy [11].

About 10% of patients with generalized myasthenia gravis do not have detectable antibodies to AChR or muscle specific kinase: double seronegative myasthenia. The presence of anti-low density lipoprotein receptor–related protein 4 antibodies (LRP4 Abs) has recently been reported in a variable proportion of double seronegative cases [12].

Striated muscle antibodies that react with muscle proteins titin and
ryanodine receptor have also been found, mainly in patients with thymoma and in those with late onset myasthenia (onset of symptoms >50 years of age). Thus, they may be helpful in the detection or recurrence of thymoma. In addition, they tend to be associated with more severe disease, and therefore may aid in prognosis [13]. Myasthenics also have an increased incidence of other autoantibodies, including antithyroid antibodies, antiparietal cell antibodies, and antinuclear antibodies, although routine screening for these is not part of the diagnostic evaluation for suspected myasthenia gravis.

**Electromyographic Studies**

The electromyographic hallmark of myasthenia gravis is a decrement in the amplitude of the muscle potential seen after exercise or slow repetitive nerve stimulation. The decrement should be at least 10% and preferably 15% or more. Routine motor and sensory conduction studies are normal, as is the conventional needle examination. The more severely affected patient is more likely to show a decremental response; responses are most consistently elicited from facial and proximal muscles. If a significant decrement is observed, exercising the muscle briefly for 10 seconds transiently reverses the decrement [14]. Single-fiber electromyography is highly sensitive, documenting increased jitter [15]—variability in the temporal coupling of single fibers within the same motor unit. Increased jitter, however, is far from specific; most peripheral neurogenic diseases also lead to increased jitter.
MISCELLANEOUS STUDIES

Myasthenia gravis may be associated with either malignant thymoma or thymic hyperplasia. Once a diagnosis is established, chest imaging should be obtained. Because there is also a significant association with thyroid and other autoimmune diseases, appropriate screening studies are indicated in the newly diagnosed myasthenic. Muscle biopsy has no role in the evaluation of myasthenia, unless there is a strong consideration of neurogenic or inflammatory weakness.
CRITICAL CARE OF THE MYASTHENIC PATIENT

Patient in Crisis

*Crisis* refers to threatened or actual respiratory compromise in a myasthenic patient. It may reflect respiratory muscle insufficiency or inability to handle secretions and oral intake, but it is typically a combination of both. With currently available treatments, myasthenic crisis is not common. An occasional patient presents with fulminating disease; crisis management then coincides with initial evaluation and institution of therapy. Otherwise, crisis may be precipitated by other illnesses, such as influenza or other infections, or by surgery.

General Measures

The respiratory function of any acutely deteriorating or severely weak myasthenic should be monitored compulsively. When the weakening myasthenic reaches a point at which increased respiratory effort is required, fatigue often prevents the effective use of secondary muscles, and respiratory failure rapidly ensues. Arterial blood gas values and even oxygen saturation are poor indicators of incipient failure in the face of respiratory muscle compromise. Forced vital capacity (FVC) and MIP are better indices and should be serially charted. The FVC should be assessed with the patient both sitting and supine, because diaphragmatic paresis may be accentuated in the supine position. MIP measurement requires special care if the patient also has significant facial weakness. An FVC less than 20 mL per kg or an MIP greater than (i.e., not as negative as) −40 cm H$_2$O suggests impending failure and usually warrants intubation. If a downward trend is noted (greater than 30% decrease) [16], elective intubation should be considered even sooner, unless there is a realistic expectation of rapid reversal.

Acute deterioration in a myasthenic always warrants consideration of contributing circumstances or concurrent illness that may accentuate the underlying defect in neuromuscular transmission. The major considerations are listed in Table 153.1 and discussed later.

The possibility of cholinergic crisis in patients receiving anticholinesterase drugs (e.g., pyridostigmine), albeit rare, should not be overlooked. The presence of fasciculations, diaphoresis, or diarrhea should alert the clinician to this possibility. In the past, the importance of differentiating between myasthenic crisis and cholinergic crisis was stressed. Edrophonium testing was used to differentiate between the two; abrupt deterioration after a conventional 10-mg test dose indicated overdosage with cholinesterase inhibitors. One had to be adequately prepared for deterioration and increased respiratory secretions. Because oftentimes it is very difficult to determine the response and because of the potential side effects with overdosage of anticholinesterase drugs of increased pulmonary secretions, many authors now recommend discontinuation of cholinesterase inhibitors at the time of crisis [2,17,18] and reinstituting them when patients are stronger. This assumes that adequate respiratory monitoring and support are in effect. A brief holiday from cholinesterase inhibition also often results in an enhanced response to therapy when reinstated.

Intercurrent infection is often associated with increased weakness in the myasthenic patient. There should be a comprehensive search for systemic infection in the deteriorating patient, particularly the patient receiving immunosuppressive therapy. Any infections should be treated aggressively. Both hypothyroid and hyperthyroid states are often associated with increased weakness. Again, there is an increased association between thyrotoxicosis and myasthenia gravis. The manifestations of electrolyte imbalance may be enhanced in myasthenic patients. Otherwise, insignificant electrolyte effects on transmitter release or muscle membrane excitability may be amplified at the myasthenic neuromuscular junction. Potassium, calcium, phosphate, and magnesium alterations should be corrected. Myasthenia gravis may also impart enhanced sensitivity to a number of medications that have only minimal effects on neuromuscular function in normal individuals. Aminoglycoside
and fluoroquinolone antibiotics, β-blockers, and many cardiac antiarrhythmics may have adverse effects. Anticholinergics, respiratory depressants, and sedatives of any kind should be avoided or used only with great caution. *Neuromuscular-blocking agents should never be administered to myasthenic patients in the intensive care unit (ICU) setting*, because they often have profound and prolonged effects. This increased sensitivity occasionally results in postoperative failure to wean in an undiagnosed mild myasthenic patient who has undergone surgery for an unrelated problem. Table 153.2 provides a comprehensive listing of medications that may further impair neuromuscular transmission in myasthenic patients.

Some attention should also be given to the general environment in which the myasthenic is managed. The typical noisy, brightly illuminated
ICU is not conducive to rest and sleep, which is crucial for the myasthenic patient in whom fatigue may be critical. Special consideration must be given to respiratory care of the myasthenic. Incentive spirometry should be avoided, because muscular fatigue outweighs any potential benefit, even in the postoperative patient. Careful attention to efficient clearance of respiratory secretions is key and can be complicated by cholinesterase inhibitors, which increase respiratory secretions. Atropine may be used to minimize this effect, but its other autonomic side effects, such as ileus, constipation, and delirium, may limit longer-term use.
Therapeutic agents used in the critical care setting parallel those available to the patient with milder myasthenia gravis. Immunosuppressive therapies are the major considerations. Any myasthenic patient in crisis, if not already receiving immunosuppressive therapy, requires it. Symptomatic therapy with cholinesterase inhibitors is now primarily used on a shorter-term basis, pending response to immunomodulating therapies. Plasmapheresis; intravenous human immune globulin; corticosteroids; and longer-term immunosuppressants and cholinesterase inhibitors are discussed individually.

Plasmapheresis

Recognition of the role of immunoglobulins in the pathogenesis of myasthenia gravis stimulated early, uncontrolled clinical trials of plasmapheresis as soon as efficient pheresis technology became available [19]. The results have been quite favorable, prompting the National Institutes of Health Consensus Conference to support its use despite the lack of controlled trials [20]. Most patients demonstrate a significant clinical response within 48 hours of initiation of plasmapheresis, although the response is short lived unless therapy is continued on an intermittent basis. The rapid response from plasmapheresis can be crucial in the face of crisis, providing a short-term reprieve during which alternative therapy can be initiated or any intercurrent medical problems resolved. Approximately 50 mL per kg should be exchanged per session [21], approximating 60% to 70% of total plasma volume. Plasma removed is replaced by an equal volume of normal saline and 5% albumin, adjusted to maintain physiologic concentrations of potassium, calcium, and magnesium. The usual course of treatment includes three to seven pheresis sessions at 24-to 48-hour intervals. Many patients develop increased sensitivity to cholinesterase inhibitors after plasmapheresis; dosage should be correspondingly reduced. The major potential complications of plasmapheresis include hypotension; arrhythmia; and hypercoagulability due to hemoconcentration. Coincident cardiovascular disease is a relative contraindication to plasmapheresis. Although plasmapheresis is too invasive to be used for long-term therapy in the majority of patients, periodic plasmapheresis has been beneficial in some patients with moderate to severe myasthenia refractory to
immunosuppressive agents [22]. Selective removal of AChR antibodies using immunoabsorption columns may also be a promising alternative to plasmapheresis, but further clinical studies are required [23].

**Intravenous Immunoglobulin (IVIG)**

Intravenous human immune globulin also frequently leads to rapid yet transient improvement in myasthenic patients [24]. Intravenous immunoglobulin (IVIG) is a therapeutic option in the event of crisis or in the perioperative period, particularly if the patient’s cardiovascular status limits plasmapheresis. Although IVIG and plasmapheresis were found to be equally efficacious in some trials [25,26], others have reported that plasmapheresis was more efficacious than IVIG; however, complications occurred more often with plasmapheresis [27]. The customary dose is 400 mg/kg/d for 5 consecutive days. More recently, a total dose of 1 g per kg was reported to be equally efficacious to 2 g per kg, although there was a trend toward slight superiority of the higher dose [28]. Maximal improvement occurred by the second week after therapy, and the therapeutic response usually persists for several weeks. Patients should be pretreated with acetaminophen and diphenhydramine to prevent flu-like symptoms that commonly occur during infusion. In addition, adequate hydration will help reduce the potential complication of thrombosis. Renal function should be checked prior to initiation of therapy, because renal failure may occur in those with renal insufficiency. Likewise, an IgA level should be obtained, because patients with IgA deficiency may develop anaphylaxis.

**Longer-Term Immunosuppression**

Corticosteroids have proven to be an effective long-term therapy for almost all myasthenic patients whose clinical manifestations cannot be well managed with low doses of cholinesterase inhibitors. Despite potential side effects associated with corticosteroid therapy, a response rate of greater than 80% supports its use [29]. Side effects can be minimized with appropriate precautions. Carbohydrate metabolism, electrolytes, blood pressure, and diet should be closely monitored; bisphosphonates (e.g., alendronate sodium, 70 mg weekly), calcium (500 to 1,000 mg per day), and vitamin D supplementation (at least 800 to 1,000 IU per day) as well are prudent to minimize osteopenia. Screening for tuberculosis exposure with skin testing and chest radiographs should be done before initiation of therapy. Occult infection must be treated or excluded for the deteriorating myasthenic patients.

Recommendations regarding corticosteroid preparation, dose, and regimen vary. Approximately one-third of patients may become transiently weaker before they improve, if given high doses of prednisone
initially [3]. Initiation with relatively low doses of prednisone and increasing in a stepwise manner has been advocated by some clinicians to minimize interim deterioration, especially if the patient is not intubated [17]. The authors prefer to begin with 15 to 25 mg of prednisone or its equivalent as a single daily dose, increasing the dose by 5 mg every second or third day until a dose of 1 mg/kg/d is reached. In the critical care setting, concurrent plasmapheresis or IVIG may offset initial steroid-related deterioration; high doses of corticosteroids (1 mg/kg/d) can be initiated in this situation, enabling a more rapid response. Oral corticosteroids are preferable, because there is a risk of developing acute steroid-induced myopathy in patients with myasthenia who are given high doses of intravenous corticosteroids [18,30].

Once maximal response is obtained, usually within 2 to 3 months, patients may be gradually shifted to alternate-day therapy by concurrently reducing the off-day dose and increasing the on-day dose, with a 10-mg shift made once each week. Some individuals note a definite off-day adverse effect; this can usually be countered with a 10-mg alternate-day dose. Once stabilized on alternate-day therapy, the on-day dose can be tapered by 5 mg per month. Many patients can be maintained in remission with as little as 20 to 25 mg of prednisone every other day (or alternating with 10 mg). Only rare patients remain in remission if therapy is discontinued, and overenthusiastic tapering of steroids is an all too common precipitant of unnecessary disability or even crisis. Myasthenia sometimes remits spontaneously, and if the patient has undergone thymectomy (see later), the probability of remission increases appreciably, making discontinuation of therapy a more realistic option.

Azathioprine is often used as an alternative agent for longer-term immunosuppression. It is effective in 70% to 90% of patients with myasthenia gravis [2] and is often initiated in patients with an insufficient response to corticosteroids, as a steroid-sparing agent, or in patients in whom corticosteroids are contraindicated [3]. Azathioprine is limited by a relatively long delay before its effects are clinically evident, up to 6 to 12 months, but its side-effect spectrum compares favorably with steroids over a time frame of many years. If a patient tolerates a 50-mg per day test dose, the daily dose can be increased by 50 mg each week up to 2 to 3 mg/kg/d. The dose is reduced if the white blood cell count is less than 3,000 per μL; an elevated mean corpuscular volume can also be used to assess adequate response [4,31]. In up to 10% of patients, an influenza-like reaction characterized by fever, malaise, and myalgias occurs within the first few weeks of therapy and resolves after discontinuing the drug [2,31]. Patients should be screened for thiopurine methyltransferase (TPMT) deficiency; those homozygous for TPMT mutations cannot metabolize azathioprine and therefore should not receive the drug. Concurrent treatment with allopurinol should also be
avoided, because it interferes with the degradation of azathioprine, thereby increasing the risk of bone marrow and liver toxicity [31].

Cyclosporine appears to be as effective as azathioprine in the treatment of myasthenia gravis [32] and is used mainly in patients who are intolerant or refractory to azathioprine. Onset of clinical improvement is quicker than with azathioprine, with most patients noticing improvement after 1 to 3 months, and becoming maximal around 7 months [33]. Its major limitations are renal toxicity and hypertension, which are seen in about one-quarter of patients. To minimize side effects, the starting dose of 5 mg/kg/d can be given in two divided doses 12 hours apart, followed by adjustments to maintain a predose trough level in the range of 100 to 150 ng per L. Subsequent adjustments can be made depending on creatinine levels and clinical improvement, with the aim to reduce the dose as much as possible, once maximal improvement is obtained [33]. Renal function (blood urea nitrogen and creatinine) must be continually monitored. Significant hypertension and preexisting renal disease are contraindications to the use of cyclosporine.

Another agent from the realm of transplant medicine, mycophenolate mofetil (CellCept), has also been used effectively for longer-term therapy. Several case series, retrospective analysis, and a small placebo-controlled, double-blind trial suggested that mycophenolate mofetil is beneficial in patients with myasthenia gravis [34–36]. Because it is better tolerated than other immunosuppressants, it has become widely used. Recently, however, two large double-blinded randomized controlled trials failed to show any benefit of mycophenolate mofetil over placebo in patients with myasthenia gravis [37,38]. One study showed that mycophenolate mofetil was not superior to placebo during a steroid taper [37], whereas the other study showed no benefit in taking mycophenolate mofetil with 20 mg prednisone compared to taking prednisone alone [38]. Several factors have been proposed to explain these surprisingly negative results including the short duration of the trials, selection of generally mildly affected patients, and the unexpected significant response to low-dose prednisone [2]. Further studies are warranted to establish the role of mycophenolate mofetil in myasthenia. Despite this, mycophenolate mofetil is still widely used in the treatment of myasthenia gravis. The standard dose is 1,000 mg twice a day, but doses up to 3,000 mg per day may be used. Monthly complete blood counts should be performed to monitor for any evidence of myelosuppression.

In refractory cases in which it has proven difficult to achieve or maintain remission, high-dose cyclophosphamide has proven effective
However, it has significant side effects including bone marrow toxicity, hemorrhagic cystitis, teratogenicity, and increased risk of infections and malignancies. Oral dosage ranges from 1 to 5 mg/kg/d. Recently, Drachman and colleagues reported dramatic clinical improvement by “rebooting the immune system” in patients with refractory myasthenia using high-dose cyclophosphamide 50 mg/kg/d for 4 days, followed by granulocyte colony-stimulating factor; clinical improvement lasted several years in some patients. Several case series have reported a beneficial response of rituximab in patients with refractory myasthenia gravis and in those with MuSK myasthenia gravis. Patients tolerated the treatment without significant side effects, making this a promising drug for the future.

**Cholinesterase Inhibitors**

Cholinesterase inhibition was the mainstay of pharmacotherapy for myasthenia gravis before the advent of immunosuppressive therapies and thymectomy. Many patients are now maintained in remission on corticosteroids or other immunosuppressive agents, whereas others, in particular, those with mild nonprogressive or purely ocular disease, require only treatment with an oral anticholinesterase drug, such as pyridostigmine (Mestinon). If an acutely deteriorating patient has been taking a cholinesterase inhibitor, the possibility of cholinergic crisis should be entertained. Overdosage of cholinesterase inhibitors may produce weakness accompanied by muscarinic symptoms such as increased pulmonary and gastric secretions; bradycardia; nausea; vomiting; diarrhea; and nicotinic symptoms such as fasciculations. Many authors advocate discontinuing anticholinesterase therapy during myasthenic crisis to minimize secretions, avoid potential exacerbation of weakness due to overdosage of cholinergic medications, and allow for easier assessment of response to other therapies. It is reasonable to reinstitute anticholinesterase therapy when patients are stronger, starting at a low dosage and gradually increasing the dose until there is clear benefit. The use of intravenous anticholinesterase therapy is controversial. Infusion of intravenous pyridostigmine at 1 to 2 mg per hour during crisis was found in one small retrospective study to be comparable to plasmapheresis. However, intravenous therapy carries the risk of dangerous side effects such as cardiac arrhythmias, myocardial infarction (due to coronary vasospasm), airway obstruction, and increased pulmonary secretions. It is therefore more prudent to hold cholinergic drugs until the patient is able to take them orally or through a nasogastric tube. If intravenous anticholinesterase therapy is deemed necessary, neostigmine and pyridostigmine preparations are
available in parenteral forms. One mg of neostigmine given intravenously is roughly equivalent to 120 mg of pyridostigmine taken by mouth. Conversion of oral pyridostigmine to intravenous pyridostigmine is 30:1.
PERIOPERATIVE MANAGEMENT OF THE MYASTHENIC PATIENT

An intercurrent problem requiring surgical intervention was a common source of major morbidity and mortality for myasthenics before the 1960s. Subsequent developments in critical care techniques, especially respiratory care, and in therapy of the underlying disease have dramatically improved this situation. Perioperative management must be compulsive, yet myasthenia gravis should rarely preclude surgical treatment that is otherwise indicated.

Preoperative Considerations

Myasthenia gravis is a major variable in surgical management, whether the surgery is elective or emergent. A neurologist (preferably the neurologist who has been managing the patient) should be considered an integral member of the operative team. If the procedure is elective, the patient’s myasthenic status should be optimized before anesthesia and surgery. Pulmonary function tests should be reviewed in detail; if respiratory or bulbar muscle function is compromised, therapy adjustments should be undertaken to improve respiratory muscle strength. All therapeutic options should be considered, with the possible exception of corticosteroids. If the patient is not receiving steroids, it is prudent to forego or delay this treatment until after surgery, because corticosteroids may increase the risk of infection and retard wound healing. If the patient is already receiving corticosteroids, therapy should be continued, with a short-term increment in dose to compensate for the added stress of anesthesia and surgery. Plasmapheresis or intravenous human immune globulin is often useful in the preoperative setting, providing a transient therapeutic benefit through the preoperative and postoperative periods. Once dose and regimen are optimized, cholinesterase inhibitors may be continued up to the time of surgery. They should then be discontinued because they stimulate respiratory secretions.

It is crucial that all physicians involved in perioperative management of the myasthenic are aware of the particular medications that may accentuate the underlying defect in neuromuscular transmission. It is
appropriate to post a warning regarding specific medications on the patient’s chart, in a manner analogous to that for medication allergies. Neuromuscular blockade should be avoided during surgery unless absolutely essential; if required, the shortest-acting agents should be used at minimal doses. Accentuated and prolonged effects should be anticipated. Aminoglycoside and fluoroquinolone antibiotics should be avoided when alternatives are available. There is no clear consensus in favor of any one halogenated anesthetic agent; ether adversely affects neuromuscular transmission. Again, close attention to metabolic homeostasis cannot be overemphasized.

Postoperative Care

Postoperative care of the myasthenic patient should not differ greatly from that of other patients, provided preoperative and intraoperative management has been successful. The patient’s status before surgery is often the best indicator of the postoperative course. Intubation and mechanical ventilatory support must be continued until the patient is alert and responsive and demonstrates and maintains adequate pulmonary function. After extubation, serial pulmonary function testing is indicated. An FVC greater than 20 mL per kg and MIP less than (i.e., more negative than) −40 cm H₂O are threshold values when reintubation should be considered. If needed, cholinesterase inhibitors may be resumed as a continuous intravenous infusion until bowel function is restored and oral intake allowed. Increased sensitivity to cholinesterase inhibitors is expected after surgical procedures, especially thymectomy. Resumption at a rate of no more than one-half the preoperative equivalent is often sufficient. Subsequent adjustments should reflect clinical indices. The myasthenic whose neuromuscular function deteriorates during the postoperative period is the exception. In all probability, an intercurrent reversible factor underlies the deterioration. The spectrum of metabolic, infectious, and pharmacologic issues discussed previously should be reviewed.

Thymectomy

After several decades of controversy, there is a consensus that thymectomy favorably alters the natural history of myasthenia gravis, especially for younger patients, independent of the presence or degree of thymic hyperplasia [43]. Thymectomy should be considered early in the course of myasthenia, except in elderly, frail patients. Thymectomy remains an elective procedure, however. The myasthenic with marginal respiratory or bulbar function should be optimally treated before surgery. The perioperative management considerations discussed earlier apply to
prethymectomy and postthymectomy management. Some controversy persists regarding the appropriate thymectomy procedure. Most centers favor the transsternal approach. Although more invasive, this approach facilitates recognition and removal of all thymus tissue and avoids postoperative respiratory compromise. There are some proponents of transcervical mediastinoscopic thymectomy; in experienced hands, this remains an alternative. Thymectomy by conventional thoracotomy has no place in the treatment of myasthenia.
CONCLUSION

Respiratory failure is no longer the source of major morbidity and mortality in myasthenia gravis that it once was. When it does occur, appropriate ventilatory support and airway protection provide time for resolution of any intercurrent problems and therapy of the underlying myasthenia. Plasmapheresis and immunosuppression are usually successful; extended intensive care stays should be rare occurrences. Treatment of myasthenia gravis with steroids, immunosuppressive agents, and thymectomy usually enables these patients to lead essentially normal lives.
REFERENCES

Although preexisting neuromuscular disorders (such as myasthenia gravis and the Guillain–Barré syndrome) may cause severe weakness, leading to an intensive care unit (ICU) admission; two of the most common causes of newly acquired weakness arising in the ICU setting—also designated “intensive care unit acquired weakness” (ICUAW)—are critical illness myopathy (CIM) and critical illness polyneuropathy (CIP) [1–3]. CIM is probably the major contributor to severe ICUAW, causing most instances of failure to wean from a respirator in patients with severe systemic diseases in the ICU, whereas CIP affects 70% to 80% of patients with severe sepsis and multiorgan failure [4]. Even experienced clinicians have great difficulty distinguishing between the myopathy and the polyneuropathy of intensive care, especially because the two conditions often coexist in an individual patient [4–6]. In the sections that follow, we discuss each disorder and comment on the differential diagnosis of severe weakness arising in the ICU setting.

**CRITICAL ILLNESS MYOPATHY**

**Diagnosis**

The hallmark of CIM is weakness that is typically diffuse in distribution, affecting both limb and neck muscles [4,7]. As is typical of most myopathic disorders, weakness tends to have a proximal predominance
in the limbs, but it may also involve distal muscles profoundly. Tendon reflexes tend to be depressed but present; however, on occasion they may be markedly attenuated or absent, possibly owing to a generalized reduction in membrane excitability that occurs with sepsis \[4\]. There may be facial muscle involvement, and rarely, extraocular muscles are affected \[6\]; other muscles supplied by cranial nerves are usually spared. A serious and common complication of the myopathy is failure to wean from a ventilator owing to marked weakness of the diaphragm. Although the majority of affected patients are adults, severe myopathic muscle weakness may occur in children who receive organ transplants \[8\], and also in critically ill children admitted to the Pediatric ICU \[9\].

**Risk Factors**

CIM develops in up to one-third of patients treated for status asthmaticus in the ICU; and in this population, intravenous corticosteroids and neuromuscular blocking agents are considered major risk factors \[6\]. Occasionally, the myopathy develops in patients who have received high-dose corticosteroids alone, without neuromuscular blocking agents, or in patients who have received neither corticosteroids nor neuromuscular blocking agents, but the latter group typically has severe systemic illness with multiorgan failure and sepsis \[4\]. Overall, CIM accounts for 42% of weakness among patients in the surgical and medical ICU setting \[10\].

**Laboratory Studies**

Serum creatine kinase (CK), electromyography (EMG), and muscle biopsy are the most important and revealing studies in the diagnosis of ICU-acquired muscle weakness. Although an elevated CK level usually helps to support the diagnosis of myopathy as the cause of weakness in an ICU patient, in CIM, the CK rise is only found in about 50% of affected patients, and occurs early in the course of the illness, peaks within a few days of onset, then declines back to the normal range \[6,7\].

**EMG Studies**

With nerve conduction studies, motor responses are typically low-amplitude or absent; and when responses can be elicited, the motor response durations are commonly increased substantially—an important clue to the presence of CIM. This is caused by slowing of muscle fiber conduction velocity and reduced excitability of the sarcolemmal membrane \[6\]. By contrast, sensory responses are relatively preserved, with amplitudes that are >80% of normal in two or more nerves (although they may be reduced when ICU polyneuropathy coexists with
CIM). Sensory responses may also be reduced initially in association with sepsis and increase during clinical recovery [11]. Needle electrode examination shows fibrillation potential activity in resting muscle of some patients. On voluntary muscle activation, motor unit potentials are short in duration and polyphasic in form with early recruitment, but when there is severe weakness or encephalopathy the patient may be unable to contract muscles sufficiently to permit analysis of motor unit potentials. Patients with CIM demonstrated by direct muscle stimulation may have electrical inexcitability of the muscle membrane caused by myopathy [12,13]. In clinical practice, stimulation of the anterior tibial muscle and the peroneal nerve at the fibular head can be informative. In CIM the ratio of the amplitude of the muscle response to peroneal nerve stimulation is >0.5, and often nearly the same as with direct anterior tibial muscle stimulation-evoked response. When weakness is because of CIP, direct muscle excitability is normal, but the nerve-evoked response is less than half as large [6].

When there are any clinical or electrodiagnostic features that are atypical for CIM (e.g., prominent cranial nerve involvement as might be seen in myasthenia gravis, or autonomic dysfunction as in botulism) it is important to consider an alternative primary, or a coexisting, disorder of neuromuscular transmission. Repetitive nerve stimulation (2 to 3 Hz) studies for a decremental response as in myasthenia, and rapid rate (30 to 50 Hz) stimulation looking for evidence of post-synaptic facilitation as in botulism, may be helpful for the evaluation of the patient.

**Muscle Biopsy**

Muscle biopsy is usually not necessary to establish the diagnosis of ICU myopathy in patients with a stereotypical clinical presentation, and typical nerve conduction and needle examination findings of CIM. The muscle biopsy for CIM discloses muscle fiber atrophy, especially involving the type II fibers; a variable degree of muscle fiber necrosis, and the absence of any inflammatory cells. The hallmark of the disorder—loss of myosin—can be confirmed immunocytochemically or by electron microscopy as reduction in myosin–adenosine triphosphatase reactivity in nonnecrotic fibers [4,11]. Severity ranges from “cachectic myopathy” (a relatively mild myopathy without major structural damage) to a more severe myopathy with thick filament loss, and even the most severe myopathy with pronounced necrotizing features [14].
Pathophysiology

Myosin loss and muscle fiber necrosis contribute to persisting weakness. Myosin loss is characteristic of CIM; corticosteroids often cause the loss of myosin, but other agents that block the neuromuscular junction in ICU patients contribute as well [7,11]. Consistent with this hypothesis, patients with myasthenia can develop loss of myosin thick filaments after receiving high-dose corticosteroids [15]; and an animal model of dexamethasone plus denervation preferentially depletes thick filaments, with reduction in muscle fiber size [16]. Some systemically ill patients who are not exposed to corticosteroids or neuromuscular blocking agents, with metabolic acidosis and multiorgan failure, can also develop CIM. Acidosis may stimulate glucocorticoid production; increase muscle protein degradation; and trigger thick filament loss [7]; likewise, inflammation; immobilization; the endocrine stress response; mitochondrial dysfunction; nutritional deficits; and compromise in the microcirculation of muscle tissue can cause impaired protein synthesis [2,3,17,18].

Treatment

The treatment of CIM is symptomatic: treating the underlying systemic illness and discontinuing or minimizing corticosteroids and neuromuscular blocking agents to the extent possible. There is evidence from two large trials that intensive insulin therapy reduces electrophysiologic signs of CIM and CIP; and high quality evidence that it reduces duration of mechanical ventilation, ICU stay and 180-day mortality [19], but hypoglycemia remains a major concern [3].

Outcomes

When the patient survives their systemic illness, recovery occurs over weeks to months, depending on the severity of the myopathy [7]. For patients whose disease severity was pronounced and for those with concomitant CIP, recovery is expected to take many months, along with the need for tracheostomy and long-term ventilatory support. In these patients some motor recovery ultimately occurs; but they will likely be left with residual long-term muscle weakness and atrophy, with compromise in daily functioning and ambulation. CIP is the main contributor to persistent disability; and in cases of CIM with coexisting CIP, it is CIP per se that impedes recovery [3]; CIM in isolation can be associated with complete recovery [4, 20].
CRITICAL ILLNESS POLYNEUROPATHY

Diagnosis

Patients with CIP develop a symmetrical, sensorimotor axon-loss polyneuropathy [4] most prominent in the lower extremities, with depressed or absent reflexes. Facial muscles are usually not affected helping to distinguish this disorder from the Guillain–Barré syndrome where bilateral facial paresis occurs in >50%. In most cases of CIP, distal muscles are affected more than proximal muscles, but when the disorder is severe there is generalized flaccid weakness and ventilatory failure. There is usually distal sensory loss of pain, temperature and vibration sense in patients alert enough to be tested [4]. Many patients with CIP have a concomitant encephalopathy from their underlying multiorgan system failure, sepsis, or both [4].

Risk Factors

Sepsis and multiorgan failure are the main risk factors for CIP [3]. One prospective study that assessed patients clinically and electrophysiologically found that 70% of patients had evidence of an axonal polyneuropathy on average 28 days after onset of sepsis and multiorgan failure [21]. Approximately 50% of patients admitted to the ICU with sepsis and multiorgan failure for at least 2 weeks will have EMG evidence for an axon-loss polyneuropathy.

Laboratory Studies

EMG Studies

The most important diagnostic test for CIP is the EMG which shows an axonal polyneuropathy with reduced—and in severe cases, absent—sensory and motor responses. The nerves of the lower limbs are often more affected than those of the arms owing to the length-dependent distribution of pathology. Nerve conduction velocities are generally normal or only mildly reduced as is seen in axonal neuropathies[6]. Nerve conduction studies of the phrenic nerves will generally reveal reduced responses. In CIP the direct muscle stimulation-evoked response of the anterior tibial muscle is relatively higher than the response elicited by peroneal nerve stimulation; the ratio of the amplitude of nerve stimulation-evoked muscle response compared to direct muscle stimulation-evoked response is <0.5. Needle electrode examination
reveals typical features of acute denervation—positive sharp waves and fibrillations—and reduced recruitment of motor unit potentials. More pronounced changes are seen in distal than in proximal muscles. Nerve biopsy is rarely indicated in evaluating a patient with suspected CIP, unless another treatable etiology is suspected. Nerve histology in CIP shows distal axonal degeneration of motor and sensory fibers; muscle shows atrophy of both type I and type II fibers [4]. Skin biopsies show loss of intraepidermal nerve fibers and reduction in sweat gland innervation indicating small fiber pathology in the acute phase of critical illness [22,23].

Pathophysiology

The polyneuropathy is a complication of the systemic inflammatory response triggered by sepsis, severe trauma, or burns [4]. It may be caused by impaired microcirculation causing reduced nerve perfusion, edema, hypoxia, and breakdown in the blood–nerve barrier. The neuropathy may also be caused by damage from cytokines, or by insulin resistance causing hyperglycemia with damage to mitochondria [4]. Abnormal nerve excitability, caused by sodium channel inactivation may cause reversible weakness for some patients [3,24].

Treatment

Treatment is symptomatic and supportive, with stabilization of critical medical and surgical conditions and vigorous treatment of sepsis. No specific treatment reduces the incidence and severity of CIP (or CIM) [4]. Although intensive insulin treatment of hyperglycemia reduces the incidence of electrophysiologic signs of CIP and CIM, mortality is greater in patients treated to strict normoglycemia [3].

Outcome

Recovery of sensory and motor function occurs over weeks to months, depending on the severity of the neuropathy. In some instances of very slow recovery over months, long-term ventilatory support may be required, even after the underlying critical illness has resolved. Compared to patients with CIM, those with CIP tend to have a slower and less complete recovery. 88% of CIM patients recovered in 1 year compared with 55% of patients with CIP or CIP and CIM combined [20]. Survivors of CIP may be left with painful dysesthesias from the small fiber
neuropathy [22].
Other peripheral neuropathies, neuromuscular junction disorders, and myopathies may present with acutely evolving weakness and simulate CÎM or CIP [6,25]. Among the acute and severe polyneuropathies, the most common acute and severe polyneuropathy is the Guillaumin–Barré syndrome (GBS) (see Chapter 152). Two-thirds of patients have had a preceding viral or bacterial syndrome, an inoculation or recent surgery. Most patients present with rapidly progressive areflexic paralysis beginning in the legs and spreading proximally; the diaphragm is involved in 25% of cases and the facial muscles in more than 50%. Most patients’ EMGs reveal a demyelinating polyneuropathy with slowed nerve conduction velocity to <70% of normal, partial conduction block; prolonged distal motor latencies; and prolonged or absent late responses, distinguishing GBS from CIP. In most patients with GBS, the cerebrospinal fluid (CSF) examination shows an albuminocytologic dissociation (elevation in protein without pleocytosis) distinguishing GBS from CIP in which the CSF findings are normal. Guillain–Barré syndrome, an immune-mediated disorder, responds to intravenous γ-globulin or plasma exchange (unlike CIP or CÎM which do not), making early recognition essential in an effort to start treatment early and reduce morbidity.

Peripheral neuropathy may be seen in some patients up to 30 days following a surgical procedure. Unlike CÎM or CIP, these postsurgical axonal neuropathies are clinically heterogeneous, presenting as focal, multifocal, or diffuse (polyradiculoneuropathy) disorders [26]; and unlike CÎM or CIP, magnetic resonance imaging (MRI) of nerves, roots, and plexuses shows inflammatory changes. These neuropathies often respond to immunotherapy.

The most important neuromuscular junction disorder causing acute weakness is myasthenia gravis (see Chapter 153). Most individuals present with ocular muscle weakness with ptosis and diplopia, and generalized weakness with a fatigable component. More than 90% of patients have antibodies to the acetylcholine receptor, and abnormal EMG findings, with a decremental motor response during repetitive nerve stimulation at 2 to 3 Hz.

Another neuromuscular junction disorder is prolonged neuromuscular blockade by muscle relaxants, nearly always seen in patients with renal or hepatic failure. It is often associated with elevated levels of the metabolite of vecuronium, and tends to improve after infusion of an acetylcholinesterase inhibitor.

Botulism is a presynaptic disorder characterized by rapidly progressive,
diffuse, symmetrical weakness with a proximal predominance; dysarthria and dysphagia; respiratory involvement; and a prominent autonomic component (dilated pupils, bradyarrhythmia, ileus, orthostatic hypotension, and urinary retention). Management consists of supportive care and administration of trivalent antitoxin.
Severe generalized weakness with failure to wean from mechanical ventilation; preserved reflexes and sensation; a transient rise in CK; and relatively preserved sensory responses on EMG suggests ICU myopathy rather than neuropathy [27]. With ICU polyneuropathy, sensory loss; areflexia; and the EMG findings of an acute neuropathic disorder are typical. Clinically, a polyneuropathy may easily be missed because in many patients detailed sensory examination is impossible in the ICU setting, especially if there is a coexisting encephalopathy. Further confounding the distinction, reflex loss can occur in both CIP and myopathy; fibrillation potentials may be found in both disorders, and motor unit potentials may not be elicitable owing to severe weakness or encephalopathy. In the final analysis, it may be difficult to distinguish one disorder from another in an individual case; and it is likely that in many patients both disorders are present in varying degrees [6,28], giving rise to a combined syndrome of CIM and CIP.

Neuro-Oncologic Problems in the Intensive Care Unit

NORMAN SCOTT LITOFSKY • YAW SARPONG

INTRODUCTION

Neuro-oncology encompasses the care of patients with neoplasms affecting the brain, spinal cord, and peripheral nervous system. These tumors may arise either within the nervous system itself or spread from systemic malignancies. Neuro-oncology patients may require care in an intensive care unit (ICU), following surgery—if they suffer catastrophic or near catastrophic neurologic decline; or if they are at high risk to suffer such a change. Lastly, neuro-oncology patients may also suffer from medical processes that require intensive care.

These issues include: elevated intracranial pressure (ICP); hydrocephalus; seizures; postoperative complications; spinal neoplastic disease; and medical systemic complications.
ELEVATED INTRACRANIAL PRESSURE

Elevated ICP frequently complicates the course of patients with both primary and metastatic cerebral neoplasms. Patients with aggressive brain tumors often succumb as a consequence of uncontrollable elevations in ICP.

Pathophysiology

Normal ICP ranges between 5 and 15 cm H₂O. This pressure is generated by the volumes of the various components contained in the “closed box” of the skull, including brain parenchyma; cerebrospinal fluid (CSF); extracellular water; and blood in vascular spaces. A perturbation of any of these components can increase ICP. Any additional tissue not normally present in the brain, such as a primary or metastatic tumor, or a hemorrhage associated with a tumor, can also increase intracranial pressure. Although the numerical value of the intracranial pressure cannot be ascertained by neuro-diagnostic images, some of the perturbations are evident on either computed tomography (CT) scan or magnetic resonance imaging (MRI).

Brain tumors can affect each intracranial component. In addition to the bulk owing to the neoplasm itself, cerebral neoplasms produce vasogenic edema [1], secondary to increased permeability of blood vessels within or adjacent to the tumor, thereby increasing extracellular fluid [2,3]. Radiographically, this edema results in hypodensity on CT or hyperintensity on T2-weighted MRI around the enhancing bulk of tumor. Tumor mass, or brain parenchyma displaced by tumor, may obstruct CSF pathways, causing hydrocephalus. Rarely, some brain tumors (choroid plexus papillomas and carcinomas) may produce excessive CSF which can cause hydrocephalus and thereby increase intracranial pressure [4] (Hydrocephalus is discussed in detail below). Intravascular blood volume also can increase in patients with tumors as a result of vasodilatation from hypoventilation. Hypoventilation can occur with seizure activity or ICP elevation, both of which can reduce respiratory drive. Hypoventilation increases pCO₂, causing arterial vasodilation, thereby increasing intravascular volume and intracranial pressure. This can cause a positive feedback loop by further reducing ventilatory drive.

Signs and Symptoms

Elevated intracranial pressure can cause variety of symptoms and signs, which do not necessarily correlate with the degree of elevated pressure,
though generally the higher the intracranial pressure, the more severe the neurologic findings.

As ICP increases, compression of the reticular activating system depresses the patient’s level of consciousness. This tends to occur sequentially, with the patient progressing from an awake and alert status to progressively more lethargic states and eventually to coma. Patients may develop varying degrees of cognitive changes including disorientation, short-term memory impairment, decreased fund of knowledge, and loss of insight and judgment.

As increasing ICP exceeds 19 mm H\textsubscript{2}O, approaching the pressure of the central retinal vein, the patient usually loses spontaneous venous pulsations typically seen on routine funduscopic examination. Further elevation of ICP may cause swelling of the optic disks (papilledema). Papilledema usually occurs over several days. A patient with long-standing papilledema may have constriction of his/her visual fields and/or decreased visual acuity.

Brain masses causing elevated ICP can cause brain shifts from one intracranial compartment to another. Usually a brain shift, also known as a “herniation,” is away from the mass causing the elevated ICP. Supratentorial masses may cause the brain to herniate inferiorly through the tentorial incisura. With a resulting central diencephalic herniation syndrome, the patient experiences simultaneous bilateral pupillary dilation from compression of the tectum, containing the Edinger–Westphal nucleus of the oculomotor nerve (CN III). A lateral cerebral mass, particularly in the temporal lobe, forces the uncus of the temporal lobe to herniate through the incisura, causing compression of CN III between the posterior cerebral artery and the superior cerebellar artery, with unilateral pupillary dilation. In both herniation syndromes, the constrictive phase of the light reflex can also cease to function (unreactive pupils). Usually, though not always, decrease in the patient’s level of consciousness precedes pupillary dysfunction.

Patients can also have light-near dissociation. Pressure on the tectum can compress the retino-tectal fibers that are part of the afferent limb of the pupillary light reflex; the pupil does not constrict to light well. Fibers involved in the afferent limb of pupillary accommodation to near vision, which travel to the tectum through other pathways, are not affected, and pupils may constrict to accommodation but not to light if the patient is sufficiently alert. This finding is a very subtle sign of elevated intracranial pressure.

Double vision may be present. The abducens nerve (CN VI), which
controls abduction of the eye, has the longest intracranial course of the cranial nerves and is at highest risk of dysfunction when ICP is elevated. Diplopia is usually more pronounced on lateral gaze, either unilaterally or bilaterally.

As the dura and blood vessels are stretched by elevated ICP, the patient may experience headache, frequently described as “band-like” or “pressure-like.” It tends to occur more commonly in the early morning and may wake the patient from sleep. During sleep, the recumbent position decreases venous return to the heart, elevating ICP, and hypoventilation that occurs during sleep also elevates ICP, increasing the headache.

Not uncommonly, headache is associated with projectile vomiting owing to pressure on the area postrema.

Patients with elevated ICP often experience neurologic deficits from compression by the tumor mass on adjacent neural structures. These deficits can include hemiparesis; aphasia; visual field loss; hearing loss; ataxia (truncal or appendicular); and sensory loss. The presence of these findings is based on the size, location, and rapidity of growth of the mass. Slower growing tumors allow the brain to compensate; focal findings may not be evident until late in the patient’s course.

Management

Mechanical and pharmacologic therapies are available to treat elevated ICP, with reduction or elimination of its manifestations. Some require very minimal intervention, whereas others are much more intensive or invasive.

Head elevation is perhaps the easiest treatment available, increasing venous drainage from the brain, and reducing intracranial blood volume. Head elevation poses minimal risk to the patient; although cerebral perfusion could be diminished, it is negligible in a patient with normal blood pressure.

Furosemide (Lasix), a loop diuretic, rapidly reduces systemic circulating volume. Extracellular and intracellular water in the brain are drawn into the vascular system and are redistributed. Lasix also promotes venous pooling, leading to similar redistribution of fluids. Lasix is generally used as an initial resuscitative dose of 1 mg per kg in patients with cerebral herniation. Risks are minimal in this setting, because electrolyte abnormalities are unlikely to occur with only a single dose. In a patient who has had frequent vomiting and is already dehydrated, Lasix can cause hypotension from loss of cardiac preload.

Mannitol, an osmotic diuretic, draws fluid out of the brain and into the vascular system by increasing serum osmolarity. From the vascular spaces, the fluid follows the mannitol as the kidney excretes it, reducing
intracellular and extracellular water in the brain. Furthermore, mannitol improves blood flow, perfusing ischemic areas of brain adjacent to the tumor mass better [5]. Mannitol is frequently given as an initial resuscitative dose of 1 g per kg, followed by 0.25 g per kg every 4 to 6 hours to maintain the diuresis and control ICP. Mannitol is quite effective in lowering ICP and/or reversing early cerebral herniation. It may also be used if patients have significant mass effect identified on neuro-imaging studies to stabilize and improve their condition (Fig. 155.1). A number of potential risks are present with long-term mannitol use. Hypotension can occur in already hypovolemic patients. Patients can also become hyperosmolar and hypernatremic. Therefore, mannitol is usually withheld from the patient if serum osmolarity exceeds 320 mOsm per L.

![FIGURE 155.1 A: This MRI, performed on a patient presenting with headache and memory lapses, shows an enhancing mass (T) involving the corpus callosum and right parietal area, with surrounding edema (E). Stereotactic biopsy revealed glioblastoma multiforme. B: One week following biopsy, the patient was admitted to the ICU with obtundation and left hemiparesis. His CT shows increased edema (E) and right-to-left midline shift (S)—parafalcine herniation. He required mannitol; increased Decadron; and surgical decompression to improve. MRI, magnetic resonance imaging; ICU, intensive care unit; CT, computed tomography.](image)

Hypertonic saline (2% to 23.4% NaCl) can be used as an osmotic diuretic for increased ICP. Similar to mannitol, the infusion of saline in the intravascular space increases intravascular osmotic pressure, drawing fluid from the intracranial extracellular spaces into the vascular spaces, and decreasing intracranial pressure. Additionally, hypertonic saline increases arterial blood pressure; cerebral blood perfusion; blood flow;
brain tissue oxygen (\(\text{PbO}_2\)), and brain tissue pH. Hypertonic saline may be better for decreasing ICP and may maintain its effects longer than mannitol [6]. Studies comparing the use of mannitol and hypertonic saline in patients undergoing brain tumor surgery show that hypertonic saline patients experience increased brain relaxation, need less fluid, and had normal to higher serum sodium [7,8]. Moreover, these studies suggest that hypertonic saline exerts its effect by reducing edema. Potential risks in the usage of hypertonic saline include cardiac arrhythmias, hypokalemia, acute hypotension with rapid infusion, and the neurologic side effects of rapid increase of serum sodium, including seizures; confusion; lethargy; and osmotic demyelination syndromes [9].

Glucocorticosteroids improve symptoms of elevated ICP and/or mass effect in patients with cerebral neoplasms by stabilizing cell membranes and reducing vasogenic edema [10,11]. Dexamethasone is the most commonly used glucocorticosteroid. An initial dose of 10 to 20 mg is followed by 4 to 6 mg every 4 to 6 hours, depending on the severity of the patient’s clinical condition. Solu-Medrol (100 mg initially, and then 20 to 40 mg every 4 to 6 hours) is another option. Glucocorticosteroids are the medical mainstay of brain tumor care because their effects are sustained over time. A patient with vasogenic edema from tumor may require steroids for a significant period of time. Steroids can cause hyperglycemia and exacerbate diabetes mellitus, changing the patient’s insulin requirements. Gastrointestinal hemorrhage or ulceration can occur; \(\text{H}_2\) blockers such as Pepcid, Zantac, or Tagamet are frequently given prophylactically. The stimulatory effect of steroids frequently disrupts sleep. Long-term use of steroids may be associated with proximal muscle weakness; avascular necrosis of the femoral head; easy bruising; and findings of Cushing’s syndrome.

Hyperventilation, reducing blood \(\text{pCO}_2\), causes cerebral vasoconstriction, which reduces the arterial intravascular blood volume within the brain. Hyperventilation can rapidly reduce intracranial pressure and reverse a cerebral herniation syndrome. Although initial hyperventilation can be performed with an AMBU bag, sustained hyperventilation requires endotracheal intubation and mechanical ventilation of the patient. Moderation of hyperventilation is necessary because at \(\text{pCO}_2\) less than 25 torr, cerebral ischemia may result from profound vasoconstriction. A vasodilatory rebound from hyperventilation occurs after approximately 24 hours, thereby negating its positive effects if hyperventilation is used chronically [12].
One of the most effective means of rapidly reducing intracranial pressure is to drain CSF. Such a maneuver is effective whether or not the patient has hydrocephalus. In a patient with a brain tumor, the safest method of draining CSF is to place a ventriculostomy, a catheter usually passed into the frontal horn of the lateral ventricle via a small hole drilled through the skull. The procedure can be performed by a neurosurgeon at the bedside. After placement of a ventriculostomy, drainage of CSF into a bag at bedside can reduce ICP. The catheter can also be coupled to a pressure transducer so that ICP can be measured. Usually, CSF is drained if ICP exceeds 15 to 20 mm Hg. The risks of the procedure include hemorrhage and infection. Therefore, coagulation studies are appropriate before the procedure is done, especially in patients who have received recent chemotherapy. The longer the catheter remains in place, the higher the risk of infection. Sometimes, prophylactic antibiotics are used.

PbO$_2$ can also be monitored, using a device such as the Licox intracranial pressure monitor (Integra Neuroscience, Plainsboro, New Jersey) which monitors ICP and brain temperature, as well as PbO$_2$. The rationale behind this monitoring tool is to provide clinicians in the operating room (OR) or ICU information regarding oxygen supply and utilization in specific tissue beds [13], alerting clinicians to areas that are at increased risks for brain damage due to hypoxia. Tissue that might already be dead because of the tumor/its reactive changes can be differentiated from tissue that might be at risk from ischemia owing to the pressure exerted by the tumor mass and its associated edema. Combining this information with the measured ICP can assist in tailoring management of these patients in the neuro-critical care setting or the OR to detect and prevent secondary ischemic events promptly. One drawback of the device relates to concerns regarding its accuracy and reliability [14].

The best means of controlling ICP long-term is to remove or shrink the tumor when possible. Unfortunately, some tumors are unresectable. Gliomas or metastases of the thalamus or basal ganglia are generally not resected except in unusual circumstances. In these instances, medical management is necessary to control ICP until adjuvant therapy, such as radiation therapy, can shrink the tumor and reduce its edema producing capabilities. The same rationale applies in patients with multifocal cerebral masses; patients with more than one metastasis do not usually have multiple operations to resect each tumor, especially if symptoms are controllable with steroids. For patients with persistent hydrocephalus, CSF shunting can be performed as a permanent CSF diversion. In performing a shunt, a neurosurgeon can introduce a catheter into the ventricles and tunnel it subcutaneously into the abdomen or pleural space. Further, an adjustable valve is added to control the rate of CSF drainage. This drainage method decreases the risk of infection associated
with prolonged usage of ventriculostomy. On the other hand, this procedure exposes the patient to risks associated with invasive surgical maneuvers, such as hemorrhage, stroke, device failure, infection, and pneumothorax [15].

If the tumor is resectable, its removal can relieve the brain of the extra mass, relieve obstruction to the flow of CSF, and reduce vasogenic edema. In addition to relieving the signs and symptoms of elevated ICP, tumor resection can also relieve the effects of compression on the surrounding brain, improving lateralizing findings. Some tumors can be removed completely. These include meningiomas, vestibular schwannomas, craniopharyngiomas, pituitary adenomas, and some metastatic tumors. Microscopic disease may still be present in the tumor bed, particularly in the case of metastases or craniopharyngioma, which may require adjuvant therapy, but ICP can be well controlled. Primary glial neoplasms, however, cannot be completely removed in most cases. The bulk of tumor can be resected, and postoperative neuro-diagnostic images may show no residual tumor, but most of these tumors have infiltrating fingers of tumor that are still present. Even so, debulking the tumor can alleviate elevated ICP, even if it is only partially removed.
HYDROCEPHALUS

Brain tumors often cause hydrocephalus, a situation in which the patient has an increased volume of CSF under increased pressure. Hydrocephalus is typically associated with enlargement of the ventricular system (or a portion thereof) and compression of the normal brain parenchyma. A patient with hydrocephalus may require urgent or emergent intensive care monitoring and treatment. Hydrocephalus is a special case of elevated ICP and warrants a unique approach.

Etiology

Hydrocephalus can occur from a variety of mechanisms in patients with brain tumors. The definitive treatment of hydrocephalus is often based on its specific mechanism of formation.

Carcinomatous meningitis, caused by leptomeningeal infiltration by tumor cells in the subarachnoid space, can prevent the absorption of CSF by the arachnoid granulations, either by occluding the granulations or preventing the flow of CSF from the outlet foramina of the fourth ventricle to the granulations. Metastatic tumors from the lung, breast, lymphoma, and leukemia are the most frequently involved systemic tumors; primary tumors behaving in this fashion include primitive neuroectodermal tumors (i.e., medulloblastoma), ependymoblastoma, and glioblastoma multiforme. A patient with carcinomatous meningitis will frequently have a stiff neck or cranial neuropathy in addition to symptoms and signs of elevated ICP.

Large extra-axial “benign” tumors, usually in the posterior fossa, can cause hydrocephalus (Fig. 155.2). These tumors include those in the cerebellopontine angle, such as meningioma or vestibular schwannoma. These tumors displace the cerebellar hemisphere and obstruct the fourth ventricle to prevent adequate circulation of CSF. Rarely, a choroid plexus papilloma can emerge from the Foramina of Luschka and similarly compress the cerebellar hemisphere. Meningiomas of the clivus or tentorium can also displace CSF pathways with resulting hydrocephalus.
FIGURE 155.2 A: This MRI, performed on a patient presenting with headache and obtundation, shows an enhancing mass in the right cerebello-pontine angle (T) with displacement of the fourth ventricle (V) to the left. B: Additional views of the MRI show hydrocephalus, with enlarged, rounded ventricles (V) and transependymal spread of CSF (C). A ventriculostomy to drain CSF was placed to temporize the patient prior to surgery. C: After resection of the tumor, a meningioma, the fourth ventricle returns toward its normal position. Edema (E) in the cerebellar hemisphere is still present. D: Hydrocephalus has resolved, with the ventricle (V) returning to normal size and shape. MRI, magnetic resonance imaging; CSF, cerebrospinal fluid.

Some tumors may originate in a ventricle or protrude into a ventricle and occlude CSF pathways, thus producing hydrocephalus. These tumors include medulloblastoma; ependymoma; choroid plexus papilloma; intraventricular meningioma; colloid cyst; central neurocytoma; giant cell
astrocytoma of tuberous sclerosis; and pineal region tumors.

Parenchymal tumors often can occlude CSF pathways. Primary or metastatic tumors in the thalamus or basal ganglia can displace brain parenchyma and occlude the Foramina of Monro or the third ventricle [16,17]. Tumors in the pineal region may occlude the posterior third ventricle or cerebral aqueduct (Fig. 155.3). Brain stem gliomas or tumors in the cerebellar hemispheres can compress the fourth ventricle [18].

![Figure 155.3](image1)

**FIGURE 155.3** A: This sagittal MRI on a patient with headache, lethargy, and diffuse weakness shows an enhancing mass (T) extending from the pineal region to the fourth ventricle (V). B: Axial views show the tumor (T) compressing the third ventricle (V) with hydrocephalus. Despite an aggressive surgical resection of this glioblastoma multiforme, the patient subsequently developed recurrent hydrocephalus and required a ventriculo-peritoneal shunt. MRI, magnetic resonance imaging.

**Symptoms and Signs**

The clinical picture of a patient with hydrocephalus is frequently the same as that of a patient with elevated ICP. In fact, hydrocephalus must be considered in the differential diagnosis for causes of elevated ICP. Patients with midline masses or carcinomatous meningitis usually do not have lateralizing neurologic deficits such as hemiparesis. Patients with unilateral brain masses may develop lateralizing deficits from further compression of the previously marginally functioning brain by progressive hydrocephalus.

**Evaluation**

If hydrocephalus is suspected, evaluation should proceed promptly. Two questions must be answered—“Does the patient have hydrocephalus?”
and “What is the cause of the hydrocephalus?” Either MRI or CT can answer these questions. MRI delineates anatomic definition of the brain, and more readily illustrates the relationship of the lesion to CSF pathways, so MRI with gadolinium is the preferred study. If the patient is too ill to obtain an MRI, or MRI is not readily available, a CT scan with intravenous (IV) contrast is sufficient. The purpose of the contrast agent with either study is to characterize the location of the lesion and its relationship to CSF pathways.

**Management**

Intervention for a patient with hydrocephalus depends on the cause of the hydrocephalus, the anatomic location of the obstruction to CSF flow, and the patient’s clinical condition.

In patients experiencing rapidly progressive deterioration, such as cerebral herniation, emergent management with a ventriculostomy, to divert CSF temporarily, can improve the patient’s clinical picture. Usually, the drainage chamber is set so that the system can be opened intermittently to drain CSF for ICP greater than 20 mm Hg. Some patients, however, require a lower ICP to achieve neurologic improvement, so the system can be opened for lower pressures. Alternatively the system can be set to drain CSF continuously at a particular pressure, for instance at 15 mm Hg. ICP is then recorded on an hourly basis. This technique of CSF drainage should be approached with some caution, because large volumes of CSF can drain if the patient strains or coughs, increasing intrathoracic pressure and therefore ICP temporarily. If too much CSF drains, patients can develop subdural or intraparenchymal hemorrhages.

A patient may have only mild hydrocephalus and not be significantly impaired clinically. Emergent intervention may not be necessary, and the patient can be stabilized with dexamethasone with or without mannitol. Resection of the tumor can provide long-term treatment of hydrocephalus by decompressing the CSF pathways, particularly with posterior fossa or pineal region tumors. Timely surgery is the best approach.

Occasionally hydrocephalus does not respond to surgical decompression alone, especially if not enough tumor can be resected to decompress the CSF pathways. Alternatively, absorptive capabilities may be compromised by inflammatory process from blood or tumor products. A permanent shunt is then necessary to treat the hydrocephalus. Although tumors with malignant cells in the CSF raise a concern that intraperitoneal spread of tumor may occur via the shunt, this complication is uncommon. Persistent symptomatic hydrocephalus dictates that the shunt be placed regardless of this concern.
In a patient with hydrocephalus who has been shunted, shunt malfunction may occur [19]. Cellular debris, proteinaceous material, or normal choroid plexus can occasionally occlude a shunt, manifested by recurrence of symptoms and signs of hydrocephalus and elevated ICP. Treatment requires operative revision of the occluded portion of the shunt, usually with replacement of the ventricular catheter or the valve.

Endoscopic third ventriculostomy (ETV) can be an alternative to a shunt in cases in which the outflow of the third ventricle is obstructed if the patient has favorable anatomy. ETV is performed by using an endoscope to navigate through the lateral ventricle and the foramen of Monro to the third ventricular floor. A hole is made into the floor of the third ventricle between the infundibular recess and mammillary bodies to create a conduit into the subarachnoid space, provided that the distance between the clivus and basilar artery and the floor of the third ventricle is adequate, usually 3 to 5 mm [20,21]. Device failure is eliminated, but sometimes the ETV is not effective, and a shunt must subsequently be placed [20].

Hydrocephalus can be difficult to treat in a patient with a tumor adjacent to the third ventricle. In this uncommon situation, the lateral ventricles may not communicate with each other through the third ventricle, and in the most extreme case, the frontal horns of the lateral ventricles do not communicate with the occipital and temporal horns. A single shunt would be ineffective in relieving the CSF obstruction. A ventriculogram with intrathecal contrast placed into the lateral ventricle via a ventricular catheter can define the nature of the obstruction. The patient may require multiple ventricular catheters to drain CSF adequately. Tumors involving the medial septal structures of the brain, where this problem should be of concern, include craniopharyngioma, central neurocytoma, pilocytic astrocytoma of the hypothalamus, and glioblastoma.
Seizures are a common occurrence in patients with brain tumors. About 40% of patients with gliomas initially present to medical attention with seizure; about 55% of glioma patients have a seizure at some point in the course of their disease. Some low-grade gliomas, such as oligodendroglioma, have a very high likelihood of seizure. Approximately 20% of patients with metastatic tumors have a seizure at some time [22,23].

Seizures may be focal or generalized. A patient remains conscious during a focal seizure. The seizure may be a motor seizure in which the patient’s mouth twitches or an extremity moves uncontrollably for a period of time. With a dominant hemisphere lesion, aphasia may occur. During a generalized seizure, the patient loses consciousness. Tonic–clonic movements may occur, and the patient may lose bladder control. A patient can also experience status epilepticus, a series of seizures occurring in rapid succession with the patient not regaining consciousness between seizures. Status epilepticus is a medical emergency that is addressed in Chapter 151. Occasionally a patient can have a seizure that is not witnessed or is subclinical in activity. The patient experiences a neurologic deficit, which subsequently improves, leaving health care providers puzzled as to the etiology of the transient deficit.

A seizure can occur in a patient with a known brain tumor if the patient’s anticonvulsant medication level(s) is (are) subtherapeutic. Drug requirements may change as steroid requirements change; dexamethasone may interact with Dilantin to lower serum levels [24,25]. Serum drug levels are therefore essential. Other reasons for seizure include a change in the character of the tumor. The tumor may have grown in size [26] or a hemorrhage within the tumor may have occurred. A CT scan of the head without and with contrast helps to differentiate among these possibilities.

A less recognized seizure presentation in this patient population is nonconvulsive status epilepticus (NCSE), defined as seizure activity lasting greater than 30 minutes with the patient being alert or having a depressed (i.e., lethargic, obtunded, or comatose) level of consciousness [27]. NCSE can be diagnosed if EEG monitoring captures seizure spikes [28]. Commonly, these patients are in the ICU with depressed level of consciousness, often attributed to the presence of the intracranial mass, and thus are often mismanaged. According to recent estimates, approximately 10% of patients with depressed level of consciousness in these settings are experiencing NCSE [29]. Brain tumor patients with a
depressed level of consciousness should undergo long-term continuous EEG monitoring to increase the ability of capturing the characteristic 3 Hz interictal spikes associated with these types of seizures [28,29]. Monitoring should be continued for 5 to 10 days to increase the yield of the study [29]. Once diagnosed, appropriate antiepileptic therapy should be started.

**Treatment**

Although a single generalized seizure usually does not have long-term consequences, such an event may precipitate rapid deterioration in a patient with elevated ICP. The associated hypercarbia from hypoventilation can increase ICP substantially; a stable patient can rapidly deteriorate even to the point of developing a herniation syndrome. Hypoxia can further compromise brain function by causing cerebral ischemia, especially in the area already affected by the tumor. Prompt intervention is therefore necessary.

Maintenance of an adequate airway and reestablishment of adequate ventilation is essential. Oxygen should be provided to the patient. Intubation and mechanical ventilation may be required if the patient experiences hypoventilation.

The best medication to stop seizure activity acutely in patients with status epilepticus is Ativan. The initial dose is 2 mg IV, and the dose is repeated every 5 minutes as needed, up to a total of 8 mg or until the seizure activity stops. Should 8 mg be required, mechanical ventilation will likely be required. Dilantin (15 mg per kg IV) or phenobarbital (15 mg per kg IV) must be used acutely in conjunction with Ativan, because the Ativan is only for short-term seizure control.

Prophylactic anticonvulsants administered without a seizure having occurred are rarely indicated unless the patient is going to surgery [30]. Following a seizure, the patient should be started on an anticonvulsant, such as Dilantin. The initial dose is 15 mg per kg intravenously, with oral maintenance dosing of 300 mg before bed or 200 mg twice a day. Phenobarbital, although more sedating than Dilantin, can also be used. Both Dilantin and phenobarbital are available in intravenous forms and be used if the patient is unable to take oral or enteral medications. Tegretol, on the other hand, is only available in an oral form, so it cannot be used in status epilepticus or in patients who cannot tolerate enteral intake.
POSTOPERATIVE COMPLICATIONS

One of the most common reasons for a patient with a neuro-oncologic illness to be admitted to an ICU is for observation following a neurosurgical procedure. This period of observation may just be overnight or it may be longer, as dictated by the patient’s neurologic and/or medical condition. Although perioperative mortality is less than 2%, medical or neurologic complications may occur in up to 30% of cases; older patients and those with increased neurologic deficits are more likely to suffer these morbidities [31]. Therefore, a variety of intraoperative and postoperative complications must be recognized before the patient’s neurologic or medical status is irreversibly compromised.

To anticipate potential complications, vital signs and neuro-checks are usually taken hourly by nurses in the ICU. One of the most important components of the neuro-checks is the patient’s level of consciousness, usually denoted by the Glasgow Coma Scale (GCS) score [32,33] (See Chapter 145). Originally developed to document the level of consciousness in patients with head trauma, use of the GCS can readily, reliably, and reproducibly identify changes in the patient’s level of consciousness—either deterioration or improvement. Other components of neuro-checks include pupillary light responses, orientation, and motor function. Any decrement in function warrants prompt evaluation. Such an evaluation should include a CT scan of the head, serum electrolytes, blood gases, and anticonvulsant level(s). Other tests may be required based on the patient’s condition. Evaluation of the ICU patient for intracerebral hemorrhage or increased ventricular size can be performed at the patient’s bedside with a mobile CT scanner, and allow for rapid diagnosis for patients with acute changes in mental status. Mobile CT scanning has also been utilized intraoperatively during resection of glial tumors which may allow for more complete resection of intracranial pathology [34].

Intracranial Hemorrhage

One of the most dramatic complications occurring in the postoperative period is intracranial hemorrhage. Significant hemorrhage usually becomes evident within 6 to 12 hours after the completion of surgery. A patient can bleed into the tumor bed (Fig. 155.4), or into the subdural or epidural spaces. Traction by the brain, slackened by tumor removal; mannitol; Lasix; hyperventilation; and CSF drainage, can tear or stretch draining veins, leading to blood accumulation in the subdural space. Because the dura is separated from the bone to perform the craniotomy,
the epidural space is no longer just a potential space; rather, it is a real space into which blood can ooze from underneath the bone edges and accumulate. A patient who experiences significant hypertension or persistent coughing and “bucking” on emerging from anesthesia is at greater risk for developing a postoperative hemorrhage. Hypertension can cause bleeding from arterial-side vessels. The increase in intrathoracic pressure that occurs with coughing or bucking against the endotracheal tube can precipitate venous-side bleeding, as can thrombosis in a draining vein from manipulation.

**FIGURE 155.4** A: This MRI on a 2-year-old shows a large enhancing mass (T) in the left temporoparietal area. B: Immediately following surgery to remove the rhabdoid neuroepithelial tumor, the patient had sustained hypertension and awakened slowly from her anesthesia with a mild right hemiparesis. This CT scan shows hemorrhage (H) in the tumor bed. With blood pressure control and observation, the patient recovered to a normal level of consciousness with resolution of her hemiparesis over several days. MRI, magnetic resonance imaging; CT, computed tomography.

Postoperative hemorrhage should be suspected in a patient who fails to emerge adequately from anesthesia. Intracranial hemorrhage should also be a concern if the patient deteriorates following emergence from anesthesia and develops progressive decline in level of consciousness, pupillary abnormalities or new motor deficits. Prompt evaluation with a CT scan is indicated. Coagulation deficits, particularly in patients who have had chemotherapy recently or who have liver disease, should be ruled out with laboratory testing for prothrombin time, partial thromboplastin time and platelet count.
Should a significant intracranial hemorrhage be identified, the patient may need to return to the OR for the hemorrhage to be evacuated. Mannitol and reintubation may be required to stabilize the patient’s condition. Occasionally, if the neurologic deterioration is mild, observation or mannitol by itself may be sufficient intervention. As the blood degrades over time and edema subsides, the patient should improve clinically. Frequent follow-up CT scanning is necessary in nonoperative management to evaluate the status of the hemorrhage and surrounding brain.

Cerebral Edema

Manipulation of the tumor and adjacent brain can lead to cerebral edema. Clinical signs can appear quite similar to postoperative hemorrhage, although deficits from edema tend to occur in a more delayed fashion. Prompt treatment with mannitol and dexamethasone are indicated following a CT scan to confirm the etiology of the patient’s neurologic change.

Endocrinopathy

Pituitary tumors may be associated with hypersecretory or hyposecretory states. Other tumors in the sella and parasellar areas may also be associated with endocrinopathy, usually hypopituitarism. Surgery for tumors in these locations can cause endocrine deficits, too. Most endocrinopathies encountered in the ICU are related to pituitary hypofunction.

The major neurologically related endocrinopathy evident in the ICU setting is diabetes insipidus, most commonly after craniopharyngioma or pituitary tumor resection. It usually occurs between 18 and 36 hours following surgery. Signs of diabetes insipidus include an increase in urine output greater than 200 mL per hour for 2 consecutive hours, a corresponding drop in urine specific gravity to less than 1.005, and an increase in serum sodium to greater than 147 mEq per L. A patient who is conscious usually experiences increased thirst. Hypotension can occur if the complication is not recognized early. Treatment with DDAVP 0.25 mL (1 μg) subcutaneously or intravenously is indicated when diabetes insipidus is recognized. DDAVP is usually given twice a day. One must be cautious that the patient is actually experiencing diabetes insipidus and is not just mobilizing surgical fluids. In a patient who has had a transsphenoidal resection of a pituitary tumor, increased thirst may be present only because the patient’s nasal packs cause mouth-breathing. Diabetes insipidus is usually transient, resolving by about 72 hours.
postoperatively. For this reason, over the first several days, it is probably better to give the DDAVP only when the patient’s findings indicate that treatment is appropriate. Occasionally, diabetes insipidus may be permanent. Intranasal DDAVP 0.2 mL at night is an effective dosing regimen for these patients in the subacute to chronic phases of diabetes insipidus.

Low serum cortisol is frequently not observed acutely in the ICU, because patients are usually on glucocorticosteroids. However, after abrupt cessation of steroid treatment, a patient may experience an Addisonian crisis. Hypotension, weakness, and fatigue are the major findings. Because the steroid depletion is acute, hyponatremia, hyperkalemia, and hyperpigmentation are not generally observed. Treatment should be instituted promptly with hydrocortisone 100 mg IV every 6 hours.

Hypothyroidism usually does not become evident for at least a week following surgical injury to the pituitary gland or hypothalamus. Fatigue, lethargy, and hyporeflexia may be present. Laboratory testing shows low T4 and free thyroxine uptake, as well as low thyroid stimulating hormone. For a patient with a sellar or parasellar tumor, preoperative recognition and treatment of hypothyroidism helps prevent this endocrinopathy from becoming bothersome postoperatively.

Postoperative Central Nervous System Infections

Infections of the central nervous system are uncommon in neuro-oncology patients. Perioperative antibiotics, such as cephalothin 1 g IV just prior to the skin incision and then for several doses following surgery, reduce infection rates [35,36]. The likelihood of a postoperative infection in the absence of CSF leak in a clean operative field (one which does not involve the paranasal or mastoid sinuses) is about 0.8% [37]. Should CSF leak occur or if operative time is extended, the risk of infection increases. Infection can occur in any of the operative spaces.

A patient may develop wound cellulitis. This superficial infection is associated with erythema, induration, and sometimes wound drainage or breakdown. The patient may have a fever and/or elevated white blood cell count. This complication usually occurs within the first week after surgery. It will usually respond to anti-staphylococcal antibiotics within several days. A 10-day course of antibiotics is usually sufficient. If drainage from the wound is present, then it should be cultured to tailor antibiotics appropriately.

Bone flap infections are more involved than simple postoperative cellulitis. They tend to occur in a delayed fashion. Drainage from a breakdown in the suture line or from the scalp near the bone flap will usually be present and should be cultured. White blood count and
erythrocyte sedimentation rate are usually elevated. A CT scan of the head may show an epidural collection or a moth-eaten appearance of the bone. Parenteral antibiotics for several weeks are necessary, though usually insufficient by themselves. Because the bone flap is devascularized, removal of the infected bone flap is usually necessary to eradicate the infection. A cranioplasty can be performed 6 months after the infection has resolved to reconstitute the integrity of the skull.

Postoperative meningitis occurs infrequently, usually in the first week after surgery. Fever without another focus of infection, or a “stiff neck,” are usually present. Lumbar puncture is essential to rule out meningitis. Usually a CT scan is performed first to rule out a structural cause of the change in level of consciousness that frequently accompanies the infection. The occurrence of meningitis often necessitates the return of the patient from the floor to the ICU. If meningitis is suspected, parenteral antibiotics should be instituted immediately after lumbar puncture. If cultures are positive, or the glucose is low in the presence of a neutrophil pleocytosis in the CSF, then a 14-day course of broad-spectrum antibiotics is appropriate [38]. When the cultures are negative, the antibiotics can be stopped.

A patient with cerebral empyema or abscess after surgery for a brain tumor typically experiences headache and other symptoms and signs of elevated intracranial pressure. Lateralizing neurologic deficits are often present. A CT scan with IV contrast is essential. In subdural or epidural empyema, the dura or arachnoid usually densely enhances with an adjacent low-density fluid collection. An abscess will show ring enhancement at the surgical site, which can look very similar to the original tumor in some cases. Suspicion of empyema or abscess necessitates an urgent return to the operating room to drain the collection of pus and obtain cultures. Six weeks of parenteral antibiotics are then necessary.

Radiation-Related Complications

Most patients with high-grade primary brain tumors or metastatic tumors will receive external beam radiation as an adjuvant therapy to control tumor growth for as long as possible. Although such treatment is usually tolerated without difficulty, a patient may have worsening of his/her neurologic condition during treatment. This “early effect” worsening is usually related to cerebral edema. CT scan and MRI show an increase in low density/intensity signal around the tumor volume. The edema tends to be responsive to high dose glucocorticosteroids. Once the patient improves, steroids can be slowly tapered to usual maintenance doses.
Much more rarely, a patient may deteriorate in a delayed fashion. “Late effects” occur about 6 to 24 months after completing radiation therapy [39]. Imaging studies show intense enhancement in the area treated. It is often difficult to differentiate radiation necrosis from tumor recurrence solely on the basis of a contrast CT or gadolinium MRI as the two entities, particularly in the case of primary glioma, look similar. Single positron emitting computed tomography (SPECT) or MR spectroscopy can often be helpful in establishing the diagnosis; tumor tends to have high metabolic activity, whereas radiation necrosis is metabolically hypoactive. Sometimes, a stereotactic brain biopsy may be required to make a definitive diagnosis. High glucocorticosteroid doses are necessary to treat radiation necrosis. Mannitol may initially be required if the patient has significantly deteriorated in order to stabilize the patient and allow the steroids time to work. Occasionally, a craniotomy to remove the necrotic mass is required, as well.

Single fraction stereotactic radiosurgery is more likely to be associated with the development of symptomatic radiation necrosis than conventional external beam radiation. In radiosurgery, the patient receives a high dose of radiation to the tumor volume, sparing the surrounding normal brain. Even so, the radiation that the surrounding brain receives may exceed its tolerance if previous radiation therapy was also used. Treatment is as described above. Approximately 13% to 50% of gliomas and 10% of metastatic tumors treated with radiosurgery may require subsequent surgical decompression [40,41].
Spinal tumors are much less common than intracranial tumors. Most patients with spine tumors do not require ICU treatment. Exceptions include patients with spinal tumors involving the cervical spine or those who have had transthoracic approaches to thoracic spinal neoplasms. A patient with a cervical spinal cord tumor may have compromise of intracostal musculature or decreased diaphragmatic function with resultant inability to maintain adequate ventilation, depending on the level of the tumor. Vital capacity should be assessed every 6 hours, because its decrement will usually be noted before respiratory insufficiency occurs. A decrease below 10 to 12 mL per kg usually requires semiurgent intubation and mechanical ventilation. Once oxygen desaturation is noted, the patient decompensates rapidly, and emergency resuscitative efforts may be required.

After spinal cord surgery, a patient may experience a temporary ileus. Bowel sounds may stop and the abdomen may become distended. Frequently the patient will need a nasogastric tube. No oral or enteral intake is appropriate until the ileus subsides. Medications will need to be given parenterally.

A spinal cord tumor is not infrequently associated with development of a neurogenic bladder. The patient often requires a Foley catheter to decompress the bladder; although such intervention is necessary, it can mask the findings. Attention to urinary retention following removal of the Foley is in order. Urinary tract infections are also not uncommon, either related to long-term Foley placement or suboptimal bladder emptying. A long-term intermittent catheterization program to maintain bladder volumes less than 500 mL is necessary if urinary retention persists.
SYSTEMIC COMPLICATIONS

Not infrequently patients with neuro-oncologic primary problems will experience systemic complications necessitating evaluation and treatment in the ICU.

Deep Venous Thrombosis and Pulmonary Embolism

Patients with brain and spinal cord tumors are at risk for development of deep venous thrombosis (DVT) and subsequent pulmonary embolism (PE). Factors such as prior history of DVT, female gender, older age, high-grade lesion, poor Karnofsky score, hypertension, and Caucasian background have been shown to increase the risk of thromboembolism in this patient population [42]. Further, tumor types such as oligodendroglioma, lymphoma, glioma, mixed tumor, and metastatic lesion increase the risk of DVT/PE development in patients [42,43].

Precautions, including TED stockings or sequential leg compression boots, should be taken to prevent DVT from developing. Prophylaxis with subcutaneous heparin (5,000 units twice a day) could be started as early as postoperative day 1 [44]. However, most physicians advocate starting chemoprophylaxis at 3 to 5 days after surgery [45]. Venous duplex scanning can recognize DVT before it becomes symptomatic.

DVT should be suspected if the patient complains of leg pain or has a fever or elevated white count without a clear explanation. Venous duplex scanning of the bilateral lower extremities should be obtained to assess for development of DVT. PE usually presents with shortness of breath and chest pain. Blood gases show hypocarbia with mild to moderate hypoxia. Administration of oxygen is necessary and prompt evaluation with chest X-ray, V/Q scan, and/or spiral CT of the chest is in order.

Once identified, treatment with anticoagulation may be problematic, especially in the immediate postoperative period because of fear of hemorrhage [46,47]. However, recent studies have shown that use of anticoagulation in the immediate post-op is safe and does not lead to increased risk of hemorrhage [42]. Alternatively, patients at high risk for PE can have placement of an inferior vena cava (Greenfield) filter to prevent PE until 2 weeks have transpired from surgery. After that time, the use of anticoagulation is much less risky and is the preferred treatment.

Cerebral Infarction

About 15% of cancer patients have significant cerebrovascular pathology
noted at autopsy [48]. Patients with primary brain neoplasms are also at risk for cerebral infarction. This complication may be related to the hypercoagulable state present in patients with malignancies. Alternatively, because these patients may be older with premorbid atherosclerosis, they may suffer cerebral infarction. This event should be differentiated from hemorrhage into a tumor or progressive tumor enlargement. CT scan or MRI is essential. The issues regarding anticoagulation must be addressed as with DVT or PE. Daily aspirin is generally safe. Coumadin, if indicated, should be reserved for a patient who has not had hemorrhage into the tumor and who is at least 2 weeks post-op.

Systemic Infections

Systemic infections are not uncommon, and most often include pneumonia, urinary tract infections, or sepsis secondary to line placement. Their management does not differ in the neuro-oncology patient from any other patient in the ICU.
END-OF-LIFE IN THE ICU

Sadly, despite the variety of available therapies, almost all primary high-grade gliomas will progress and the patient harboring the tumor will succumb to the disease. A patient with metastatic brain disease may fail tumor treatments, as well. Hopefully, the patient’s physicians have discussed these possibilities as the patient begins to show signs of decline. The patient and family may decide to limit the intensity of care, and treatment in the ICU is not an issue. However, a patient may deteriorate quickly from the illness and elevated ICP before limits on treatment can be discussed and defined. When these circumstances occur, the physicians in the ICU may need to discuss limiting inappropriate technologies with the patient and family. The most intensive interventions—surgery, ventriculostomy, and intubation for hyperventilation—may be most readily decided against. Other interventions, such as mannitol, may be withheld. Sometimes, a decision is made to stop all technologies and focus on comfort. Abrupt cessation of dexamethasone generally leads to a rapid demise of the patient.

On occasion, an aggressively treated patient will continue to deteriorate. Elevated ICP can cause cardiac arrhythmias in the end stage. Prior to the onset of such cardiac difficulties, however, the patient may progress to the point of “brain death.” In the USA, the definition of brain death requires the patient be not hypotensive, not hypothermic, or on paralytic or sedative medications. The etiology of the patient’s condition should be known. The clinical exam shows the patient to be comatose, without any brain stem reflexes, motor responses, or spontaneous respirations, and on no sedative medications. An apnea test is also necessary. In this test, the patient is provided flow-by oxygen at 100% to maintain adequate oxygenation. The patient is disconnected from the ventilator and observed for the absence of respirations for 10 minutes (until a pCO₂ of 60 mm Hg is reached). Confirmatory test, such as electrocerebral silence on an EEG, or absence of brain blood flow on a radionucleotide cerebral flow study, can also be helpful [49]. If these criteria are present, the patient should be declared brain dead and supportive technologies be discontinued. It is important and mandated by statute that the organ bank be contacted so the organ donation can be discussed with the family prior to discontinuing supportive technologies.

14. Keddie S, Rohman L: Reviewing the reliability, effectiveness, and

A wide variety of neurologic problems may confront the physician in the intensive care unit (ICU), including several important disorders for which basic information is not readily available. These include:

Suicidal hanging, electrical shock, acute carbon monoxide poisoning, and decompression sickness, which present so blatantly that the diagnosis is rarely in question, yet the range of clinical manifestations and their management may be unanticipated.

Cerebral fat embolism, which is often not initially suspected if other surgical or medical issues take precedence.

Singultus (hiccups), which is an all too common secondary problem that may further weaken the severely ill patient.

Compression neuropathies, which may complicate prolonged bed rest.

**SUICIDAL HANGING**

Hanging is the second most common means of committing suicide in the USA after self-inflicted gunshot wound [1]. Introduced in 5th-century England, hanging proceeded to become the official form of execution. Early on, there was no exact procedure, and most hangings resulted in slow strangulation [2]. Changes in techniques, with the victim dropped at least his height and the hangman’s knot placed in the submental location, have produced a consistently fatal bilateral axis pedicle fracture, resulting in complete herniation of the disc and severance of the ligaments.
between C2 and C3 [3]. This injury causes almost immediate death by destroying the cardiac and respiratory centers, lacerating the carotid artery, and injuring the pharynx [2,3].

Suicidal hangings are rarely so expert, and death usually results from strangulation due to interruption of cerebral blood flow [4]. A minimal amount of compression occludes the jugular veins, whereas an increased force occludes the carotid arteries [5]. A much larger force is necessary to arrest blood flow in the vertebral arteries [5]. Pressure on the jugular veins from the noose results in venous obstruction and stagnation of cerebral blood flow, causing hypoxia and loss of consciousness [3].

Cervical muscle tone then decreases, allowing airway obstruction and arterial compression, further exacerbating hypoxia [3]. In addition, external compression of the carotid bodies or vagal sheath can increase parasympathetic tone, whereas pressure on the pericarotid area stimulates sympathetic tone; either can result in cardiac arrest [4,5]. The altered autonomic tone may also cause a release of catecholamines, resulting in neurogenic pulmonary edema, as well as affect the respiratory smooth muscle tone, causing respiratory acidosis and a further insult to cerebral oxygenation [3].

If blood flow is quickly restored, full recovery can often be expected. If the blood flow is interrupted for more than a few minutes, however, hypoxia causes cell death and cytotoxic and vasogenic edema, with increased intracranial pressure. There is selective vulnerability of the cerebral cortex (particularly the pyramidal cell layer), the globus pallidus, thalamus, hippocampus, and the cerebellar Purkinje cells to anoxia and ischemia.

**Diagnosis**

Although the diagnosis is rarely in doubt, the patient may show a range of findings, varying from rope burns to coma. In the immediate posthanging period, the patient most commonly shows evidence of an altered level of consciousness, ranging from restlessness, delirium, or violent agitation to lethargy, stupor, or coma. Seizures, and rarely status epilepticus, may occur [4,5]. Injury to the neck blood vessels occurs in 40% of patients, resulting in carotid dissection, thrombus formation, and distal ischemic infarcts [6]. Venous occlusion may lead to venous congestion, venous ischemia, and hemorrhage [7]. Development of the acute respiratory distress syndrome (ARDS) may result from central nervous system (CNS) catecholamine release, causing constriction of the pulmonary venules [3]. In incomplete hanging, the patient may also show signs of laryngeal and pharyngeal edema, resulting in hoarseness, dysphagia, and stridor [3,7]. Although infrequent in suicidal hangings, fracture of the odontoid and injury to the spinal cord may occur.
Careful neurologic examination should be performed, with particular attention to alterations in the level of consciousness and evidence of spinal cord injury, such as paraparesis, quadriplegia, or urinary retention. There should be frequent monitoring of vital signs for evidence of autonomic instability and stridor. Initial laboratory evaluations should include radiographs of the cervical spine; arterial blood gas determination; electrocardiogram (ECG); and cardiac monitoring. Computed tomography (CT) angiogram should also be considered if suspicious for dissection of the carotid artery [8].

Neuroimaging of the brain may be quite variable, from a normal head CT in many patients, to evidence of edema, hemorrhage, and ischemia. Owing to decreased blood flow and the resultant hypoxia, edema may be seen in the white matter tracts [9]. Subcortical and subarachnoid hemorrhages may result from venous occlusion, whereas ischemia may result from venous or arterial occlusion, particularly in the areas of greatest vulnerability: the basal ganglia, cortex, thalamus, and hippocampus [10].

Treatment

The patient may appear dead but might still be resuscitable. Patients quickly lose consciousness with hanging attempts, but may still have cardiac and respiratory function or can quickly regain these with prompt cardiopulmonary resuscitation (CPR). The goals of treatment are to maintain an adequate level of cerebral oxygenation, to decrease the raised intracranial pressure, and to monitor and treat any cardiac arrhythmias or respiratory distress that may develop. After hanging, the mechanical trauma induced by strangulation can also cause hemorrhage and edema in the paratracheal and laryngeal areas and result in delayed but significant airway obstruction at any time within the first 24 hours. Endotracheal intubation may be required if there is evidence of hypoxia due to ARDS, airway obstruction, or increased intracranial pressure [9].

Other concerns for victims of hangings include fractures and thrombi. A fracture of the odontoid requires immediate neurosurgical or orthopedic intervention to stabilize the cervical spine and protect the cord from injury. A carotid thrombus requires prompt vascular intervention to remove the clot and restore patency and blood flow. In addition, assessing the patient for other evidence of self-inflicted injuries and intoxications is also warranted, as is a complete psychiatric evaluation once the patient is able to cooperate.
Course

The prognosis for recovery is not immediately apparent with the first neurologic examination. Many patients have made a full recovery despite an initial Glasgow Coma Scale (GCS) score of 3 [4]. However, the fatality rate for suicidal hangings may range from 60% to 70% [11]. Indicators for a good recovery include a hanging time of less than 5 minutes, a heartbeat present at the scene or in the emergency room, CPR initiated at the scene, a GCS score greater than 3, and an incomplete circumferential ligature [4]. Predictors of a poorer prognosis include evidence of cardiopulmonary arrest, a spontaneous respiratory rate less than 4 per minute, need for intubation, and neurogenic pulmonary edema [5]. In patients who have cardiopulmonary arrest survival rate is less than 50%, with only about 12% of survivors having good neurologic outcome [12].

Other neurologic sequelae can become manifest either in the immediate posthanging period or after a relatively asymptomatic latent period. The individual may show evidence of a confusional state; a circumscribed retrograde amnesia; Korsakoff’s syndrome; or even progressive dementia [7]. Transient hemiparesis; aphasia; abnormal movements; motor restlessness; and myoclonic jerks also can characterize this period [7]. Ear numbness may result from injury to the greater auricular nerve [13]. Most patients who survive the acute phase recover to variable degrees. Three more severe delayed outcomes have also been observed: (a) comatose state with minor neurologic improvement and death; (b) early neurologic recovery, followed by cerebral edema with uncontrollable uncal herniation and severe morbidity or mortality; and (c) complete neurologic recovery, followed by delayed encephalopathy and death [3].
ELECTRICAL INJURIES

Approximately 4,000 injuries and 1,000 deaths from electrical shock occur annually in the USA. Most fatalities occur in the workplace, but a third result from contact with household current [14]. Approximately 400 people per year are affected by lightning strikes, with one-third of victims dying owing to their exposure [15].

Pathophysiology

Electrical and lightning injuries are exceedingly variable and dependent on a number of factors. Current flowing between two potentials, or amperage, is equal to the voltage divided by the resistance to current flow (I = V/R). Current is generated by either an electrical source or a lightning strike. Current may be direct (DC), as with lightning, or alternating (AC), as with most household appliances. Alternating current has a tendency to produce tetanic contractions that prevent voluntary release from the current source, thus prolonging the electrical contact time and increasing the potential for injury. Higher voltages, such as those that occur with lightning or with contact with high-voltage conductors, produce more severe injuries than those caused by lower voltages. Wet skin and tissues high in water content provide low resistance to current flow and are at a higher risk for injury, whereas tissues high in fat and air, such as hollow organs, provide high resistance. Nerves and blood vessels have lower than expected resistances, and thus are more sensitive to electrical injury than their water content would suggest [16]. Other variables that affect the severity of damage include the current pathway (i.e., whether it involves the heart, diaphragm, spinal cord, or brain), the area of current contact and exit, and the duration of contact [16].

In addition, lightning injuries are classified according to the type of exposure [17]. “Direct strikes” involve direct contact between the lightning bolt and the highest point of the victim, often the head. “Side flash” involves the spread of electricity from the lightning bolt to a nearby object and then to the patient. Side flash victims are typically exposed to less voltage and current than with a direct strike. Finally, “stride current” involves the spread of electricity from the lightning bolt to the ground and then through contact points in the patient. Stride current patients are more likely to experience spinal cord injuries, because the current crosses through the spinal cord from one limb to another.

Neurologic Complications of Electrical and Lightning
Injuries

Neurologic sequelae of electrical injuries affect both the central and peripheral nervous systems, with both immediate and long-term difficulties.

Immediate Effects

Immediate neurologic effects of electrical injuries are noted throughout the neuraxis. 10% to 50% of patients experience a brief loss of consciousness, as well as headache; retrograde amnesia; and confusion [18]. Patients with electrical and lightning injuries to the head may also suffer subarachnoid or parenchymal hemorrhages, particularly in the basal ganglia and brainstem [19]. In patients who suffer cardiac or respiratory arrest, posthypoxic encephalopathy may develop in “watershed” areas of the cerebral cortex. Less commonly, patients may present with cerebral infarction or a temporary cerebellar syndrome [19].

Catecholamine release may result in autonomic dysfunction, as evidenced by transitory hypertension; tachycardia; diaphoresis; vasoconstriction of the extremities; and fixed and dilated pupils [20]. Thus, lightning-strike victims should receive full resuscitative efforts despite pupillary changes, because these may not indicate permanent brainstem dysfunction. Lightning-strike victims may also suffer “keraunoparalysis,” a self-limited paralysis more often involving the lower extremities, accompanied by a lack of peripheral pulses, pale and cold extremities, and variable paresthesias [19]. Keraunoparalysis is presumably caused by localized vasospasm from catecholamine release.

Acute spinal cord injuries are also seen, particularly with stride current injuries. The spectrum of spinal cord injuries includes paralysis, spasticity, autonomic dysfunction, and, later, chronic pain and pressure ulcers [19]. Acute neuropathies are typically not seen with lightning strikes, but may be seen with electrical injuries in association with compartment syndromes, local burns, or vascular injury [21]. Both electrical and lightning-strike victims are vulnerable to the subacute development of cataracts, whereas lightning-strike patients are peculiarly susceptible to tympanic membrane rupture; vertigo; and hearing loss [22,23].

Delayed Effects

Delayed effects of electrical and lightning injuries may also span the neuraxis. Recognized neuropsychiatric effects include depression; posttraumatic stress disorder; fatigue; irritability; and memory and concentration difficulties [24]. Movement disorders have also been
described, such as transient dystonias, torticollis, and parkinsonism [19]. Delayed ophthalmologic and otologic consequences include cataracts, conductive and sensorineural hearing loss, and vertigo [22,23]. Delayed autonomic dysfunction may manifest as reflex sympathetic dystrophy, presenting as a limb with burning pain, cutaneous vasoconstriction, swelling, and sweating [20]. Prolonged and permanent spinal cord abnormalities may become manifest in the delayed development of a myelopathy or a motor neuronopathy [14,25]. Peripheral neuropathies may result from compression due to scarring and fibrosis from the original injury or delayed ischemia due to vascular occlusion [26]. Peripheral neuropathies are more likely to occur in areas directly involved by the electrical current, but may also occur in limbs that were not seemingly in the current path [27].

Evaluation

Initial evaluation of the electrical- or lightning-injured patient involves assessment of the scene and evaluation of safety. Disconnect electrical sources before evaluating the patient. Contrary to conventional mythology, lightning-strike victims are not electrically charged and may be examined immediately. Assessment of cardiopulmonary status is essential, because many victims suffer cardiopulmonary arrest and may recover well if CPR is initiated promptly. Cardiac arrhythmias and asystole commonly accompany these injuries, as does respiratory arrest due to passage of current through the brainstem respiratory centers. Stabilization of the spine is also essential, owing to potential spinal cord injuries and fractures from falls.

Neurologic Examination

The neurologic examination should begin with assessment of the level of consciousness. Initially, many patients are comatose, but this is often brief and followed by a period of confusion and amnesia, lasting hours to days [28]. Seizures are uncommon. The cranial nerve examination may reveal fixed and dilated pupils; blindness; papilledema; partial hearing loss; and tinnitus. Rupture of the tympanic membranes may also be present with lightning injuries to the head. Evaluation of the motor system for focal weakness and reflex changes may indicate cerebral injuries, myelopathy, or neuropathy. Cerebral lesions, caused by hemorrhage or infarction, may result in contralateral hemiparesis. Spinal
Cord injuries are more common in the cervical region and produce paraparesis or quadriparesis. Peripheral nerve injuries in the immediate assessment are typically located in areas of extensive burns. Sensory loss is less frequent than motor deficits and is maximal in burned areas.

**Laboratory Evaluation**

Laboratory evaluations should be focused on the known complications of electrical and lightning injuries. Serial determinations of electrolytes, renal function, and hematocrit are essential for assessing adequate fluid replacement. Serum creatine kinase and urinary myoglobin are useful measures of muscle necrosis. Arterial blood gases may reveal a metabolic acidosis. ECG and cardiac monitoring are used in patients with cardiopulmonary arrest or with known current pathways through the thorax, because delayed cardiac arrhythmias may develop. Radiologic examinations of the long bones, spine, and skull are indicated when fractures or deep burns are suspected based on the history and physical examination. Magnetic resonance imaging (MRI) or myelography may be used to assess spinal cord damage if signs of myelopathy are present. Cranial imaging is indicated when there is prolonged alteration of consciousness and may reveal intracranial hemorrhages, cerebral edema, or the effect of diffuse cerebral hypoxia. The electroencephalogram (EEG) is also useful to rule out status epilepticus in patients with prolonged unconsciousness. The EEG background may remain slow even when the mental status has returned to baseline. Nerve conduction studies and electromyography may be useful in localizing and following axonal and demyelinating electrical injuries to the peripheral nerves and plexi, although they are not generally used in the acute evaluation.

**Management**

Evaluation and treatment of medical concerns are essential for good neurologic recovery. Efforts should focus on circulatory volume, hydration status, renal function, acidosis, and electrolyte balance. Because high-voltage electric shock victims usually have myoglobinuria secondary to burns and deep tissue injury, their fluid needs are similar to those of crush injuries. Ultrasoundographic assessment of volume status can be helpful and urine output should be maintained at greater than 0.5 mL per kg hour. Alkalization of the urine and osmotic diuresis with mannitol also help to prevent myoglobin nephropathy.

Extensive burns due to direct current or clothing ignition are best treated in specialized burn units. At times, skin grafts are required. Debridement of necrotic muscle and fasciotomy are sometimes necessary to prevent secondary ischemia from a compartment syndrome. Amputation might be required if there is significant necrosis. For these
patients, arteriography may assist in identifying the level of viability. Tetanus prophylaxis and prevention of superinfection are also needed. Spine and long-bone fractures require stabilization.

Recurrent seizures are treated with phenytoin (18 to 20 mg per kg loading dose followed by 5 to 7 mg/kg/d). Other antiepileptics, such as levetiracetam, should also be considered. Because fluid restriction is contraindicated, patients with signs of increased intracranial pressure require osmotic diuresis with mannitol. Intracranial pressure monitoring may be useful in patients with cerebral edema. Specific treatment for electrical spinal cord injuries is not available, and early institution of physical therapy is recommended. In patients with cardiac arrest, the hypothermia protocol can be considered.

Prognosis

Prognosis is difficult to ascertain for electrical injuries to the nervous system. Patients with deficits at presentation might potentially recover fully, whereas those with delayed onset of neurologic deficits may have syndromes that progress over months to years.
CARBON MONOXIDE POISONING

Carbon monoxide is a colorless, tasteless, and odorless gas that gives no warning of its presence. It is normally present in the atmosphere in a concentration of less than 0.001%, but a concentration of 0.1% can be lethal [29]. Carbon monoxide is a byproduct of incomplete combustion and as such is found in automobile exhaust, fires, water heaters, charcoal-burning grills, methylene chloride, volcanic gas, and cigarette smoke. It is also endogenously formed from the degradation of hemoglobin, resulting in baseline carboxyhemoglobin saturation between 1% and 3% [29]. Smoking can raise the endogenous level to 6% to 7% saturation [29]. Carbon monoxide poisoning may occur in the acute and chronic setting. For further information on the pathogenesis, diagnosis, and treatment of carbon monoxide poisoning, see Chapter 178.

Diagnosis

It is important to consider carbon monoxide poisoning in the differential diagnosis of any individual who presents with an altered state of consciousness or headache, particularly in the setting of a long car ride or other exposure to poorly ventilated and incompletely combusted fuel. Of note, the carboxyhemoglobin levels are not indicative of the severity of toxicity and depend on factors such as duration of exposure, comorbid conditions, and ambient carbon monoxide concentration [30]. With mild intoxication, symptoms may include a mild headache; dyspnea on exertion; and fatigability [29]. With increasing levels of toxicity, more severe symptoms may include impaired motor dexterity; blurry vision; irritability; weakness; nausea; vomiting; and confusion [29]. At its most severe, carbon monoxide exposure may cause tachycardia; cardiac irritability; seizures; respiratory insufficiency; coma; and death [29]. In addition, there can be evidence of rhabdomyolysis, flame-shaped superficial retinal hemorrhages, and, occasionally, a cherry-red discoloration best appreciated in the lips, mucous membranes, and skin [29,31,32]. For mild carbon monoxide intoxication, in which there is no loss of consciousness and carboxyhemoglobin levels are less than 5% in nonsmokers or less than 10% in smokers, only headache and dizziness around the time of presentation were found to correlate with an increased incidence of delayed sequelae, including asthenia, headache, or decreased memory [33].
A head CT scan may be normal early on or show signs of cerebral edema as inferred from narrowed ventricles and effacement of the cerebral sulci. The degree of CT abnormalities does not predict the clinical course [34]. MRI findings may reveal diffuse, confluent diffusion-weighted imaging (DWI); FLAIR (fluid-attenuated inversion recovery); and T\textsubscript{2}-weighted (time for 63\% of transverse relaxation) hyperintensities bilaterally in the periventricular white matter, centrum semiovale [35,36], basal ganglia, particularly involving the globus pallidus, and the hippocampus [37]. The electroencephalogram usually demonstrates diffuse slowing but is generally of little prognostic value.

**Treatment**

The criteria for hospital admission include coma, loss of consciousness, or neurologic deficit at any time; any clinical or electrocardiographic signs of cardiac compromise; metabolic acidosis; abnormal chest radiograph; oxygen tension less than 60 mm Hg; and carboxyhemoglobin level greater than 10\% in individuals with pregnancy, greater than 15\% in those with cardiac disease, or greater than 25\% in all other patients [31]. All patients should be treated with 100\% oxygen as soon as the diagnosis of carbon monoxide poisoning is even considered. It should be administered through a tight-fitting nonrebreathing mask or after endotracheal intubation of severely sensorium-compromised patients. The administration of 100\% oxygen can shorten the half-life of carbon monoxide from 4 to 5 hours to approximately 1 hour [30]. Oxygen should be administered until the carboxyhemoglobin level normalizes [29]. (See Chapters 169 and 178 for a discussion of hyperbaric oxygen therapy.) Traditionally, treatment with hyperbaric oxygen was considered for treatment of carbon monoxide poisoning; however, literature reviews have shown that although it washes out carbon monoxide more quickly, there is no additional clinical benefit to hyperbaric treatment, and there may even be increased risk of neurologic harm [32].

**Course**

The delayed appearance of neurologic sequelae found in many posthypoxic states occurs with particular frequency and severity after carbon monoxide poisoning. Up to 30\% of patients may succumb to the initial exposure and 25\% may develop a progressive encephalopathy resulting in a persistent vegetative state, with a 50\% mortality rate [34]. Later sequelae may include seizures, cortical blindness, scotomas, Korsakoff's psychosis, irritability, hemiplegia, chorea, and peripheral neuropathy.

Between 10\% and 30\% of patients develop delayed neurologic sequelae,
and there are no guidelines to indicate which patients are at greatest risk [31]. Although there seems to be a rough correlation between both duration of initial unconsciousness and increasing age with the development of delayed neurologic sequelae, even patients with mild toxicity can progress to develop the tardive signs [30]. Recently, some work has looked at markers in the blood to predict neurologic damage including neuron-specific enolase and S100B with some success [32]. The post–carbon monoxide syndrome begins 7 to 30 days after the initial insult and is characterized by gait disturbances, incontinence, and memory impairment, as well as signs of parkinsonism, mutism, and frontal lobe disinhibition [29,30,38]. The development of isolated cognitive impairment has considerable variability in the literature. Some report memory dysfunction, impaired attention, and affective disorders in moderate to severe carbon monoxide exposure, whereas other studies suggest that mildly exposed individuals have no cognitive impairments compared to matched controls in neuropsychiatric testing [30,39,40].

On average, 75% of affected individuals show recovery within a year of the insult, although 20% of these individuals continue to show evidence of mild to moderate impairment of memory and extrapyramidal function [41]. Although the specific cause of the delayed syndrome is unknown, it does correlate temporally with the pathologic findings of cerebral white matter demyelination found in the chronic stages of the illness, as opposed to the largely gray matter edema, ischemia, and hemorrhagic necrosis found in the acute stage [42]. There is no specific treatment for the delayed neuropsychiatric syndrome, although symptomatic treatment, including cognitive therapies and dopamine agonists, may be of benefit in the short term [41].
Decompression sickness (“the bends”) occurs when gases dissolved in body fluids come out of solution, forming bubbles in tissues and venous blood. Situations in which decompression sickness arises include rapid ascent to the surface by tunnel workers or scuba divers, decompression or rapid ascent in an airplane, and high-altitude flying with inadequate cabin pressurization. In these situations, nitrogen and other inert gases that supersaturate the tissues under high pressure are released as bubbles under conditions of decreased pressure. As the bubbles coalesce, they may cause local tissue ischemia because of compression or venous obstruction. The microcirculation is further compromised by capillary endothelial edema; by activation of platelets, coagulation factors, and complement; and by hemoconcentration due to fluid extravasation [43,44]. Nitrogen, the largest component of inspired air, is lipophilic, and thus gas bubbles are more likely to form in the bone marrow, fat, and spinal cord. Additionally, gas bubbles may result in barotrauma to the pulmonary beds, releasing further air emboli into the venous circulation [43,44].

Symptoms of decompression sickness are variable. In most cases, the onset is within 6 hours of decompression, but may be seen later at 12 to 24 hours [43]. Fulminant cases present earlier. Any organ system can be affected, and symptoms range from a pruritic skin rash (“the creeps”), cough (“the chokes”), and joint pain to paraplegia, vertigo, altered level of consciousness, seizures, shock, and apnea.

Almost 80% of patients with decompression sickness have neurologic symptoms. The most frequent neurologic presentation is with paresthesias, which may be diffuse or focal, and result from gas bubble formation in the skin, joints, peripheral nerves, or spinal cord. Weakness, ranging from monoparesis to quadriplegia secondary to spinal cord involvement, may also occur. Cerebral symptoms are infrequent but can range from headache and lethargy to vertigo, visual disturbances, paralysis, and unconsciousness [43,44]. Vertigo, hearing loss, tinnitus, nausea, and vomiting are relatively common complaints, resulting from rupture of the cochlear and semicircular canal membranes.

Air embolism is a more serious decompression illness, and its onset is usually within 5 minutes of decompression. It probably results from tearing of the lung parenchyma secondary to overdistension, as the gases
in the lungs expand during ascent [43]. The gas escapes into the pulmonary vein and may embolize into large vessels [43]. Venous gas bubbles are effectively filtered by the lungs, but arterial embolism may also result from gas passing through a patent foramen ovale. Based on their buoyancy, the emboli often produce neurologic symptoms by floating into and occluding cerebral arterioles. Unconsciousness and stupor are the most frequent symptoms. Death from cardiopulmonary arrest may also occur. In most patients, improvement in symptoms accompanies the redistribution of the gas emboli to the venous circulation [43].

Recompression is the definitive treatment for decompression diseases. The patient should be transported in a pressurized aircraft to the nearest decompression chamber with minimal delay. (See Chapter 61 for a more detailed discussion of the management and therapy for decompression syndrome.) The Divers Alert Network also maintains a 24-hour phone consultation service to assist with diving accidents, reached at (919) 684-9111.

Remarkable recovery may occur after recompression. Delay in treatment can limit its effectiveness, but recompression should be attempted even up to 2 weeks after the onset of symptoms. Relapses requiring repeated hyperbaric treatment may occur [45]. Patients with long-term sequelae from decompression illnesses should not be reexposed to conditions that allow their recurrence.
CEREBRAL FAT EMBOLISM SYNDROME

Fat embolism syndrome is characterized by diffuse pulmonary insufficiency with hypoxemia, neurologic dysfunction, and petechiae, occurring 12 to 48 hours after trauma [46,47]. At least subclinically, fat embolism is present after all fractures involving the long bones. It is clinically recognized in 0.5% to 2% of patients with long-bone fractures and in 5% to 10% of patients who have sustained multiple fractures [48,49]. There are also reports of fat embolism syndrome occurring in the setting of orthopedic procedures, such as hip arthroplasty, intramedullary rods, and leg lengthening procedures [48,50]. There is an increased risk associated with a patent foramen ovale [49].

Pathogenesis

The two main pathogenetic hypotheses of fat embolism syndrome are the mechanical and chemical theories. The mechanical theory posits that physical disruption of bone and blood vessels at the fracture site allows free fat globules to enter venous sinusoids and then to embolize to the lungs [46]. The chemical theory proposes that a trauma-induced catecholamine surge results in lipid mobilization from the fat stores or the coalescence of chylomicrons into fat globules [46,51]. The fat emboli in the circulation may then be broken down by lipases in the lungs or systemic circulation, generating free fatty acids [46,47,52]. The toxic fatty acids stimulate the release of inflammatory mediators, increasing permeability of capillaries, generating ARDS and cerebral vasogenic edema [46,47]. Furthermore, the inflammatory mediators may increase platelet adhesion and coagulation [52]. Fat emboli, in conjunction with increased platelet adhesion, may arrest blood flow, resulting in cerebral ischemia and hemorrhage [47,52].

Cerebral fat emboli and ischemia, rather than cerebral anoxia, produce the neurologic damage seen in this condition. The brain is edematous and shows a leptomeningeal inflammatory reaction and cortical surface petechiae. Microscopically, there are fat emboli and ball, ring, and perivascular hemorrhages. The fat emboli are more prevalent in the gray matter, but the hemorrhages are more common in the centrum semiovale; internal capsule; and cerebral and cerebellar white matter [53]. Electron microscopy reveals intravascular fat vacuoles; breakdown of endothelial walls; swollen neurons; and glia [53].

Diagnosis
Characteristically, there is a symptom-free interval of 12 to 48 hours between the inciting trauma and the onset of fat embolism syndrome [46]. Altered consciousness or development of neurologic deficits after a lucid interval following trauma should alert the physician to the possibility of fat embolism. The syndrome may present as a spectrum of disability, from subclinical presentations with only a decreased arterial partial pressure of oxygen (PaO$_2$), decreased platelets or hemoglobin, to a fulminant presentation. Gurd’s diagnostic criteria for fat embolism syndrome include one or more major criteria (respiratory insufficiency, neurologic dysfunction, or petechial rash), four or more minor criteria (fever, tachycardia, retinal changes, jaundice, or renal changes), and one or more laboratory criteria (fat macroglobulinemia, decreased hemoglobin or platelets, or increased erythrocyte sedimentation rate) [47]. An alternative diagnostic scheme was proposed by Schonfeld [47], assigning a numerical score to similar criteria with a score of 5 or more suggestive of the diagnosis.

Sudden onset of fever, tachycardia, and tachypnea often herald onset of the syndrome. Respiratory distress and hypoxemia with an oxygen tension less than 60 mm Hg is common and may be the initial or only laboratory abnormality. The chest radiograph may be unremarkable for one-half of the cases, but fine stippling or hazy infiltrates of both lung fields should be sought, because they are consistent with fat embolism syndrome [51].

Petechiae are present in 50% to 60% of clinically recognized cases and are most often found on the lower palpebral conjunctivae; neck; anterior axillary folds; and anterior chest wall [47]. There is an associated thrombocytopenia, believed to be caused by the consumption of platelets with their aggregation around the embolic fat droplets, and a progressive anemia with hemoglobin levels commonly less than 9.5 g per 100 mL [51]. Retinal fat emboli and lipuria are each in evidence in more than 50% of patients [51]. The retinal emboli appear as small rosaries of microinfarcts surrounding the macula of both eyes, which over the course of the following 10 to 14 days evolve into yellowish, fatty plaques [51].

The CNS manifestations range from confusion to coma, and although they almost always accompany respiratory insufficiency, they can be the initial and sometimes only symptomatic manifestation of fat embolism syndrome [47]. Impaired consciousness is the earliest recognizable sign. The symptoms can begin with restlessness and confusion and may evolve gradually or abruptly to stupor and coma. Coma, especially if it develops abruptly, portends a poor prognosis [46]. Focal or generalized seizures can occur and may antedate the onset of coma [47]. Decerebrate rigidity is found in up to 15% of cases, and pyramidal signs of hyperreflexia and extensor plantar responses are found in 30% to 70%. Focal neurologic signs, such as aphasia and hemiparesis, are usually restricted to patients
with more severe disturbances of consciousness [47].

Neuroimaging of cerebral fat embolism syndrome reveals diffuse vasogenic and cytotoxic edema, as well as areas of hemorrhage and infarct, and these imaging findings are seen to evolve over time. The most common finding on head CT is evidence of diffuse brain edema, as shown by small ventricles and flattened sulci [54]. Brain MRI has been described to show five different patterns associated with cerebral fat emboli [55]. These range from acute findings of scattered embolic appearing ischemia to chronic changes with demyelinating changes and atrophy. Other changes include confluent cytotoxic edema, vasogenic edema, and petechial hemorrhages. The T₂ hyperintensities that appear as small subcortical foci in gray and white matter, indicative of vasogenic edema, are correlated with lower GCS scores [56].

**Treatment**

Rapid immobilization of fractures and their early definitive management decreases the likelihood of fat embolism syndrome [51]. Sequential clinical examinations, chest radiographs, and arterial blood gas determinations for patients believed to be at high risk may help identify early on those needing more aggressive care. These patients should have early and expedient replacement of fluids and blood and administration of 40% oxygen by mask [51].

The support of respiration and maintenance of arterial oxygen levels greater than 70 mm Hg sometimes requires intubation and mechanical ventilation. Steroids have been advocated as treatment to blunt the inflammatory response, to help preserve vascular integrity, and to minimize interstitial edema formation, but there are as yet no controlled trials demonstrating a consistent benefit. A brain CT or MRI is indicated to assess whether there are any direct cerebral traumatic injuries accounting for neurologic symptoms.

**Prognosis**

Mortality in fat embolism syndrome can reach 10% to 20%, but recent improvements in management have lessened this rate [57]. Twenty-five percent of patients experience permanent neurologic deficits [53]. A favorable prognosis is more likely with normal muscle tone, active deep tendon reflexes, and retention of appropriate pain response [47]. If patients survive the pulmonary insufficiency, neurologic dysfunction is
often reversible [47]. A worse prognosis is portended by coma, severe ARDS, pneumonia, or congestive heart failure [46].
SINGULTUS (HICCUPS)

Hiccups are usually a benign and self-limited condition. Prolonged hiccups can produce fatigue, sleeplessness, weight loss, depression, difficulty in ventilation, and, in postoperative patients, wound dehiscence [58]. In intubated patients, persistent hiccups may result in hyperventilation and respiratory alkalosis [58].

Pathophysiology

Hiccups result from a sudden reflex contraction of the diaphragm, causing forceful inspiration, which is arrested almost immediately by glottic closure, producing the characteristic sound. Afferent pathways include the vagus and phrenic nerves and thoracic sympathetic fibers (T₆ to T₁₂). The efferent pathway includes the phrenic nerve to the diaphragm, the vagus nerve to the larynx, and the spinal nerves to the accessory muscles of inspiration. Although central control of this reflex is not well defined, it probably involves lower brainstem and upper cervical spinal levels, including the respiratory center, phrenic nerve nuclei, medullary reticular formation, and hypothalamus [59].

Etiology

Hiccups may result from a multitude of causes, owing to injury or irritation of the afferent or efferent pathways or disease within the central control mechanism. Hiccups most frequently result from irritation of the stomach wall or diaphragm, leading to impulses along the phrenic and vagus nerves. Abdominal disorders causing hiccups include gastric ulceration, gastric distention, gastroesophageal reflux, hiatus hernia, cholecystitis, peritonitis, subdiaphragmatic abscess, ileus, and bowel obstruction. Thoracic disorders that precipitate hiccups include esophagitis, pericarditis, myocardial infarction, pneumonia, and neoplasm. More proximally along the course of the nerves, neck masses, such as neoplasm and goiter, may also result in hiccups. Brainstem neoplasm or ischemia, multiple sclerosis, arteriovenous malformations, and meningoencephalitis are CNS causes [60]. Perioperative causes include neck extension, intubation, visceral traction, and intraoperative manipulation of efferent or afferent nerves [58]. Metabolic disorders, such as uremia, electrolyte abnormalities, alcohol intoxication, diabetes mellitus, and general anesthesia, have also been implicated [58,59]. Medications, most frequently corticosteroids and benzodiazepines, may also induce hiccups [61,62]. Hiccups have been reported in four patients
with Parkinson’s disease, and dopamine agonists appeared to play a causative role [63,64]. Some patients have idiopathic or psychogenic hiccups.

Evaluation

A history of gastrointestinal, cardiac, pulmonary, or CNS complaints or surgery may assist in determining the etiology of intractable hiccups. The physical examination should rule out inflammation or neoplasm in the thorax, abdomen, CNS, and neck. Chest and abdominal radiographs are obtained routinely, and fluoroscopic evaluation of the diaphragm is sometimes needed. Radiographic or endoscopic evaluation of the gastrointestinal tract is sometimes warranted. If the CNS is implicated, cranial CT or MRI may be useful. Electrocardiography (ECG) is required. Other investigations include determinations of electrolytes, renal function, glucose, creatine kinase (if myocardial infarction is suspected), and a toxicology screen for alcohol and barbiturates. Lumbar puncture is required if there is a suspicion of CNS infection. Electromyography may be useful if surgical therapy for hiccups is contemplated. Careful review of medications for potential causative agents is indicated.

Management

Initial management includes identification and treatment of disorders that may cause hiccups, such as inflammation, infection, or gastric dilatation. When this is unsuccessful, nonpharmacologic and pharmacologic treatments are available for intractable hiccups.

Nonpharmacologic therapies alter the reflex arc responsible for hiccups. Pharyngeal stimulation may resolve hiccups, either by nasogastric intubation, swallowing dry granulated sugar, or by the introduction of a red rubber catheter through the mouth or nares, followed by a jerky to-and-fro movement [58]. Pharyngeal stimulation tends to be a temporary measure. Counterstimulation of the vagus nerve by pressure on eyeballs, rectal massage, or irritating the tympanic membrane may also alleviate hiccups [59]. Breathing into a paper bag, gasping with fright, Valsalva maneuver, and supramaximal inspiration possibly abolish hiccups by interrupting the stimulus for respiration or increasing the carbon dioxide concentration [65]. If nonpharmacologic therapies are ineffective, drug therapy should be initiated. Baclofen 5 mg orally three times a day, increased to 10 mg three times a day, has been effective in decreasing and potentially eliminating hiccups [59]. Alternatively, chlorpromazine taken 25 to 50 mg orally or intramuscularly three or four times a day has also been effective. If this is ineffective in 2 to 3 days, then a slow intravenous infusion of chlorpromazine 25 to 50 mg in 500 to 1,000 mL of normal saline is
indicated. Although hypotension may result from intravenous (IV) administration, chlorpromazine may be most effective by this route [60]. If IV chlorpromazine is ineffective, it should be discontinued and 10 mg of metoclopramide given orally four times per day. Other medications used in refractory patients include haloperidol (5 mg three times per day), anticonvulsants (e.g., gabapentin, phenytoin, carbamazepine, and valproic acid), amitriptyline, nifedipine, nimodipine, and amantadine [60].

Most patients respond to mechanical or drug therapy. In refractory cases, transcutaneous stimulation of the phrenic nerve, transesophageal diaphragmatic pacing, vagus nerve stimulation, phrenic nerve block or ablation, or microvascular decompression of the vagus nerve may be useful [60,66,67]. Because there are multiple efferent pathways involved, hiccups may remain even after phrenic nerve ablation.
Compression neuropathies are common in the general population. In the ICU population, several nerves are particularly at risk, compression of which may result in delayed morbidity [68]. The ulnar nerve may be compressed in the condylar groove posterior to the medial epicondyle when the arms are positioned in a flexed, pronated, or semipronated fashion, or when the flexed elbows are used by the patient for repositioning. Ulnar nerve palsy causes weakness of the intrinsic muscles of the hand, and numbness of the fourth and fifth fingers. The peroneal nerve is also at risk where it courses around the fibular head. The everted immobile position of the leg in severely weak or paralyzed patients contributes to its vulnerability. Other compression neuropathies and brachial plexopathy may result from positions assumed during prolonged coma before hospitalization. Hematomas resulting from clotting disorders; anticoagulation; local injection; arterial puncture; or phlebotomy may also compress the peripheral nerves and plexi [69]. Evaluation of compression neuropathies includes an electromyography (EMG) to localize the lesion [68]. Proper positioning of the limbs to avoid compression of these nerves between the bed and bony prominences is key to prevention.

PSYCHIATRIC ISSUES IN INTENSIVE CARE
JOHN QUERQUES
Chapter 157

Diagnosis and Treatment of Agitation and Delirium in the Intensive Care Unit Patient

JASON P. CAPLAN

“... patients are attacked with insomnolency, so that the disease is not concocted; they become sorrowful, peevish, and delirious; there are flashes of light in their eyes, and noises in their ears; their extremities are cold, their urine unconcocted; the sputa thin, saltish, tinged with an intense color and smell; sweats about the neck, and anxiety; respiration, interrupted in the expulsion of the air, frequent and very large; expression of the eyelids dreadful; dangerous deliquia [syncope]; tossing of the bed-clothes from the breast; the hands trembling, and sometimes the lower lip agitated. These symptoms, appearing at the commencement, are indicative of strong delirium, and patients so affected generally die, or if they escape, it is with a deposit, hemorrhage from the nose, or the expectoration of thick matter, and not otherwise. Neither do I perceive that physicians are skilled in such things as these; how they ought to know such diseases as are connected with debility, and which are further weakened by abstinence from food, and those aggravated by some other irritation; those by pain, and from the acute nature of the disease, and what affections and various forms thereof our constitution and habit engender, although the knowledge or ignorance of such things brings safety or death to the patient.”
In *On Regimen in Acute Diseases*, Hippocrates identified agitation as a harbinger of severe illness and poor outcome [1]. His admonition that physicians understand the causes and treatments of agitation remains vital today, for the safety not only of patients but also of hospital staff attending to them. Nowhere is this more pertinent than in the intensive care unit (ICU) and its finely balanced environment of invasive and often delicate treatment modalities, interference with which is rarely as easily corrected as is “tossing of the bed-clothes.” The sudden pulling of precisely placed central lines, intra-aortic balloon pumps, or endotracheal tubes can carry profound consequences for patients and those responsible for their care.

The term “ICU psychosis” has unfortunately entered common medical parlance in reference to agitation and confusion in the ICU patient [2]. This misnomer is inaccurate for several reasons. Classifying agitation as psychosis is usually diagnostically incorrect; moreover, drawing an etiologic connection between the patient’s geographic location and the development of agitation is nonsensical. Historically, sensory deprivation and interruption of normal sleep patterns alone were thought to result in behavioral disturbances in the ICU, but modern research has not confirmed this relationship [2]. The causal attribution of mental status changes to the environment of the ICU is dangerous because it obviates the need for further diagnostic inquiry that could reveal a previously unidentified pathologic process. As with all new symptoms, careful diagnosis is the first step toward effective treatment.

This chapter reviews the causes, presentations, and treatments of common causes of agitation in the ICU patient, focusing on delirium.

**DELIRIUM**

Perhaps the most common cause of agitation in the general hospital as a whole, and the ICU in particular, delirium is a neuropsychiatric manifestation of a systemic disturbance (*Table 157.1*) [3]. As such, the paramount task in its treatment is the identification of its underlying cause(s).

**TABLE 157.1  Diagnostic Criteria for Delirium**

- Alteration of consciousness and attention
- Change in cognition (e.g., memory deficit, disorientation, language or perceptual disturbance) that is not due to dementia
Development over hours to days
Fluctuation during the course of the day
Precipitation by a medical condition or its treatment

Epidemiology

Prospective studies of all patients admitted to the ICU regardless of pathology have found incidence rates of delirium of 31% on admission [4] and 82% when limited to the population requiring intubation and mechanical ventilation [5].

A diagnosis of delirium exacts a profound toll on both the immediate and long-term well-being of patients and the economic resources required for their care. One study of mechanically ventilated patients in the ICU demonstrated significant increases in length of hospital stay and 6-month mortality, even after adjustment for age, severity of illness, comorbidities, coma, and medication exposure [5]. Another study of patients—limited to those who did not require mechanical ventilation—found that a diagnosis of delirium independently predicted longer hospital stay, even after correction for relevant covariates [6]. When framed in fiscal terms, delirium has been associated with 39% higher ICU costs and 31% higher hospital costs overall [7]. Delirium predicts greater hospital costs across multiple domains, including professional, technical, consultative, and nursing [8].

Disruptive behavior poses a grave risk of acute injury to the delirious ICU patient because of the extensive use of invasive technology in the ICU. This hazard has been specifically studied in patients who extubate themselves. Restlessness and agitation—two of the most frequent concomitants of delirium—individually predict self-extubation that can result in laryngeal and vocal cord trauma, emesis, aspiration, cardiac arrhythmia, respiratory arrest, and death [9].

Etiology

An exhaustive review of conditions that may precipitate delirium would likely cover the breadth of medical and surgical practice. Given the near limitless number of possible etiologies, when searching for a possible cause of delirium, it often proves useful to scan the clinical data searching for broad categories of pathology. The mnemonic “I WATCH DEATH”
(Table 157.2) lists the processes most commonly related to delirium; the mnemonic “WWHHHHIMPS” (Table 157.3) aids recall of immediately life-threatening causes.

With complicated conditions requiring interventions on multiple fronts, patients in the ICU are often subjected to polypharmacy. A review of the patient’s medication list with an eye toward certain categories of medications frequently causative of, or contributory to, delirium is warranted (Table 157.4). Particular offenders include anticholinergics, antihistamines, corticosteroids, opioids, and benzodiazepines [10,11].

Pathology

Alertness is subserved by the ascending reticular activating system (RAS) and its bilateral thalamic projections; attention is mediated by neocortical and limbic inputs to this system \[12\]. Structural or neurochemical interference with these pathways could theoretically result in the deficits in alertness and attention that are the hallmarks of delirium. Because the primary neurotransmitter of the RAS is acetylcholine, the relative deficit of cholinergic reserve in the elderly (e.g., due to microvascular disease or atrophy) may be the neural basis of the heightened risk of delirium in the geriatric population. Medications with anticholinergic activity are likely to disrupt this system’s functioning even further.

---

In the setting of impaired oxidative metabolism, dopaminergic neurons have been found to release excess amounts of dopamine; its subsequent reuptake and extracellular metabolism also are disrupted. Because, at high levels, dopamine is theorized to facilitate the excitatory effects of glutamate [13], this dopaminergic hypothesis constitutes a proposed mechanism for the agitation seen in delirium. In fact, oxidative dysfunction predicts increased risk of delirium [14].

Risk Factors and Detection

Risk factors for delirium can be divided into three broad categories: properties of the illness (acute physiologic), preexisting properties of the patient (chronic physiologic), and properties of the environment (iatrogenic) (Table 157.5) [15].

The majority of patients suffering from delirium present with the hypoactive subtype. Withdrawn and psychomotorically retarded, the patient with hypoactive delirium is frequently thought by caretakers and family to be depressed. Although these patients cause little disruption to the ICU environment and provoke less acute distress in their caregivers, they are no less subject to the adverse outcomes of an altered sensorium. Although the immediate threat to safety may be less apparent in these cases, hypoactive delirium can rapidly and unpredictably evolve into acute agitation as a result of unchecked, upsetting delusions. Moreover, the subjective experience of hypoactive delirium is as intense and distressing as the agitated variety [16].

Two delirium screening scales have been validated for use by nonpsychiatric personnel in the ICU. The Confusion Assessment Method for the ICU (CAM-ICU) features a four-domain assessment that can be administered in less than 1 minute [17]. Both sensitivity and specificity are >90%, and it has been translated into several languages. The Intensive Care Delirium Screening Checklist (ICDSC) features eight items, each scored present or absent. Sensitivity and specificity of the ICDSC are 99% and 64%, respectively. The minimal time required to complete either of these scales allows for scoring several times daily, which is an important feature, given the waxing and waning nature of delirium. One comparison study of these scales found the CAM-ICU to be a superior predictor of increased length of stay and mortality [18]. Both scales are available at www.icudelirium.org. Careful screening and early detection can limit the sequelae of delirium and forestall the additional consequences attendant to the evolution of hypoactive delirium into agitation.

Diagnostic Evaluation

In ambiguous cases of delirium, an electroencephalogram (EEG) may provide objective data to aid diagnosis. Although the association of delirium and EEG changes was first described in the 1940s, no objective test since has demonstrated better performance in accurately detecting delirium. In their classic studies, Engel and Romano described three landmark electrographic findings in delirious patients: generalized slowing, consistency of this slowing despite wide-ranging underlying conditions, and resumption of a normal rhythm with treatment [19]. For all presentations of delirium, generalized slowing in the delta-theta range
(delta: 0 to 4 Hz, theta: 4 to 8 Hz), poor organization of the background rhythm, and loss of reactive changes to eye opening and closing are considered diagnostic [20]. Recent studies have estimated the sensitivity of EEG in the diagnosis of delirium to be approximately 75%, with false-negative results likely a result of slowing not sizable enough to drop the patient’s baseline rhythm from one range to the next.

EEG may also prove helpful in discerning the etiology of a delirium, since delirium tremens (DTs) as a result of alcohol or sedative–hypnotic withdrawal is associated with low-voltage fast activity superimposed on slow waves, while sedative–hypnotic toxicity is associated with fast beta activity (>12 Hz) [20]. EEG may also detect previously undiagnosed deliriogenic conditions, including nonconvulsive status epilepticus, complex partial seizures, or cerebral lesions that may act as seizure foci.

Once delirium is confirmed, the search for an underlying medical cause should commence. A careful step-by-step approach can help prune a near-endless list of possible etiologies. Although no evidence-based protocol of diagnostic studies most likely to identify a culprit exists, broad-based, relatively inexpensive, and noninvasive laboratory testing can often be informative (Table 157.6).

In most circumstances, psychiatric consultation can be beneficial to the patient and the consultee. A consultation psychiatrist’s familiarity with delirium and its causes and treatments can speed diagnosis and intervention. Delay in psychiatric consultation has predicted lengthier hospitalization [21].

### Pharmacologic Management

The definitive treatment of delirium is the identification and treatment of the underlying cause(s). In addition, numerous interventions may reduce its potentially harmful sequelae.

### Cholinergic Agents

Given the hypocholinergic/hyperdopaminergic neurophysiological model of delirium, the intuitive goals of pharmacologic treatment are to increase cholinergic and decrease dopaminergic activities. By reversibly inhibiting metabolism of acetylcholine, the cholinesterase inhibitor physostigmine has been shown to reverse delirium resulting from multiple etiologies, but its clinical utility is limited by its brief duration of effect and a narrow therapeutic window. Therefore, physostigmine is usually used only when

delirium is known (or highly suspected) to be caused by anticholinergic toxicity, for which it is considered the agent of choice [22]. Some small studies and case series of dementia-treating cholinesterase inhibitors have demonstrated possible delirioprotective effects [23,24], but these agents’ utility in the acute setting is hampered by their long half-lives and subsequent extended interval before therapeutic serum levels are reached. Two randomized, double-blind, placebo-controlled trials failed to demonstrate any benefit of donepezil in either preventing or treating postoperative delirium [25,26]. An additional randomized, placebo-controlled trial of rivastigmine for delirium prevention also failed to demonstrate any such benefit [27].

**Haloperidol**

As dopamine receptor antagonists, neuroleptics are theoretically suited to the task of dampening dopaminergic activity. Through decades of clinical experience and published data, haloperidol, a butyrophenone neuroleptic, has shown itself to be the agent of choice in the treatment of acute delirium [28,29]. It is ideal for use in the ICU since it can be administered by the oral, intramuscular (IM), or intravenous (IV) route. Although the U.S. Food and Drug Administration (FDA) has not approved the IV administration of haloperidol, FDA regulations permit the use of any approved drug for a non-approved indication or by an unsanctioned route in the context of innovative therapy. IV administration is preferable to the oral and IM routes for multiple reasons, including improved absorption; limitation of pain as a consequence of injection; minimization of apprehension on the part of the patient; and lower frequency of extrapyramidal side effects (EPS), including acute dystonia, parkinsonism, and akathisia [30]. Although there is no standard dosing regimen for the use of IV haloperidol, treatment is usually initiated with a bolus dose ranging from 0.5 mg (in the elderly) to 10 mg (for severe agitation). A 30-minute interval should be observed between doses to gauge the effect of the previously administered dose. If the initial dose does not achieve the desired effect, then the next dose can be effectively doubled until appropriate sedation is achieved (i.e., 1, 2, 5, 10 mg, and so on). Although a randomized, double-blind comparison trial did not support the use of benzodiazepines alone for the management of delirium (except when due to alcohol or sedative-hypnotic withdrawal), IV lorazepam in doses of 1 or 2 mg can be coadministered with haloperidol to achieve more rapid sedation [31]. The combination of haloperidol and lorazepam has been shown to allow for lower total doses of each drug [32] and to further reduce the frequency of EPS [33]. Complete absence of agitation should be targeted, and the regimen
should be adjusted to achieve this goal. Once agitation is effectively quelled, haloperidol can be given two or three times daily, with additional doses provided as needed for breakthrough agitation. The total dose can be gradually decreased; it is usually wise to wean the evening dose last to provide prophylaxis for “sundowning.”

**Side Effects of Haloperidol.** As with all pharmacologic interventions, the use of haloperidol is not without risk. Neurologic sequelae—EPS, seizures, neuroleptic malignant syndrome (discussed in detail in Chapter 185), and tardive dyskinesia—all have been associated with the chronic use of haloperidol. In practice, however, these are rare and are minimized by IV administration [30]. Of these neurologic symptoms, akathisia is often most problematic in the setting of delirium since the sense of having to be in motion at all times is noxious, tiring, and likely to exacerbate agitation. Treatment with β-blockade is often effective. In clinical practice, haloperidol’s reported lowering of the seizure threshold appears negligible for those without seizures [34].

Hypotension, a rare complication, is easily detected by routine monitoring in the ICU. Haloperidol has been shown in some cases to prolong the QT interval, resulting in increased risk for torsade de pointes with increased risk for death [35,36]. An electrocardiogram should be ordered to measure the baseline corrected QT (QTc) interval, and serum potassium, magnesium, and calcium levels should be checked and monitored [28]. Once treatment begins, a QTc >500 ms or an increase >25% from baseline may warrant telemetry, cardiological consultation, and reduction or discontinuation of haloperidol. In these cases, it is advisable to calculate the QTc manually, since the automated reading may overestimate the value and result in the needless interruption of necessary treatment. The minimization of other drugs with the potential to prolong the QTc also should be considered to allow the ongoing effective treatment of delirium. Other antipsychotics, including the newer agents, also have been associated with QT prolongation [37].

**Other Dopamine Receptor Antagonists**

Droperidol, the other member of the butyrophenone family of neuroleptics, had been used extensively for the treatment of delirium, but its use was constrained by the 2001 FDA-mandated black-box warning regarding QT prolongation, torsade de pointes, and death [38].

Phenothiazines, the other major class of so-called conventional or first-generation neuroleptic medications (e.g., chlorpromazine, fluphenazine,
thioridazine, mesoridazine, perphenazine, and trifluoperazine), are poorly suited to the treatment of delirium due to sedation, anticholinergic effects, and α-adrenergic blockade.

Most of the so-called atypical or second-generation neuroleptic agents have been studied in the treatment of delirium. A variety of single case reports, case series, retrospective analyses, and open-label studies have found these medications to be safe, well tolerated, and effective. Randomized, controlled trials have demonstrated that risperidone, olanzapine, and quetiapine are effective for decreasing the severity of symptoms of delirium [39–44]. A randomized, controlled trial of ziprasidone did not show benefit in delirium, though this study was limited by measurement of delirium as a binary state (present or absent) rather than its severity [45].

Quetiapine may have a niche role in the treatment of delirium in patients with Parkinson’s disease or Lewy body dementia, since its action at various subtypes of dopamine receptors is less likely to exacerbate these disorders [46]. Paliperidone may occupy a similar niche role in patients with hepatic compromise since it does not require significant hepatic metabolism [47]. The strict regulation of clozapine due to the risk of agranulocytosis precludes its routine use in delirium.

In 2005, the FDA required that a black-box warning be placed on all atypical neuroleptics indicating an increased risk of death when used to treat behavioral problems in elderly patients with dementia and, in 2008, broadened this warning to encompass conventional neuroleptics. In addition, risperidone, olanzapine, and aripiprazole carry warnings regarding a potential increased risk of cerebrovascular events in elderly patients with dementia-related psychosis. The benefits of neuroleptics in treating delirium often outweigh their risks.

Other Pharmacologic Interventions in Delirium

Dexmedetomidine is a selective α₂-adrenergic receptor agonist used as a sedative and analgesic in the ICU. A number of randomized, controlled trials have demonstrated a significantly lower incidence of delirium when ICU patients were sedated with dexmedetomidine compared with midazolam, lorazepam, or propofol [48–50]. An additional study comparing dexmedetomidine with morphine found a comparable incidence but a shorter duration of delirium with dexmedetomidine [51]. A randomized, open-label trial comparing dexmedetomidine infusion with IV haloperidol for the management of delirious intubated patients demonstrated significantly shortened time to extubation and length of ICU stay with dexmedetomidine [52]. Despite the relatively high cost of the drug, two studies have demonstrated it to be cost-effective due to the offset of time spent ventilated, time in the ICU, and the sparing of other
expensive sedating agents [50,53].

The 5-HT-3 receptor antagonist ondansetron has been reported to be successful in managing symptoms of delirium in postcardiotomy patients [54]. The mechanism of this effect is uncertain, but 5-HT-3 receptors have been shown to play a role in cognition, and ondansetron has also demonstrated affinity for the opioid mu receptor and for sodium channels [55].

Randomized, Controlled Trials of Pharmacotherapy in Delirium

Randomized, controlled trials of pharmacotherapy in delirium are summarized in Table 157.7. Many of these interventions demonstrate efficacy in limiting, but not eliminating, symptoms of delirium. Since the definitive treatment of delirium requires identification and treatment of the underlying cause, it may not be reasonable to expect that a neuroleptic will completely eradicate all symptoms of a delirium to the point that it is undetectable. Rather, neuroleptics are intended to manage the symptoms of delirium and to reduce the likelihood of harm to the patient or ICU staff.

extrapyramidal side effects not seen with olanzapine.

Scheduled quetiapine resulted in more rapid resolution of delirium, reduced agitation, and improved rates of transfer to home or a rehabilitation facility. Both groups received as-needed intravenous haloperidol.

Both agents reduced the severity of delirium without a significant difference between the groups.

All three agents reduced the severity of delirium without a significant difference among the groups.

Both agents reduced the severity of delirium. Response to risperidone was poorer in patients older than 70 years.

All patients were mechanically ventilated. Neither neuroleptic significantly decreased duration of delirium.

Both agents reduced the severity of postcardiotomy delirium.

No significant difference was found in duration of delirium between the groups. A significantly higher number of patients in the placebo arm required open-label addition of neuroleptics due to symptoms of delirium.

**Prevention**

A number of randomized, controlled trials have examined the use of
medication in the prophylaxis of delirium. These are summarized in Table 157.8. A meta-analysis of five of these studies supported the use of neuroleptics as prophylaxis against delirium [64].

Specifically pertaining to postoperative delirium, one randomized, controlled trial of 921 elderly patients undergoing major noncardiac surgery found that operative anesthesia with bispectral index (BIS) monitoring reduced propofol delivery by 21%, volatile anesthetics by 30%, and postoperative delirium by 35% as compared to routine operative anesthesia [65].

A number of multicomponent non-pharmacological protocols have been established to formalize nursing and environmental approaches to delirium prevention. A meta-analysis of these studies concluded that they are effective in decreasing the incidence of delirium and preventing falls with a trend toward lowering length of stay [66].
OTHER CAUSES OF AGITATION

Dementia is a predisposing risk factor for the development of delirium. The demented patient, however, is also at risk of becoming agitated in the ICU as a result of unfamiliar surroundings and possible delusional beliefs. Behavioral measures should be employed to help the patient orient to the milieu. In cases of acute agitation, haloperidol is the treatment of choice; however, in cases of Lewy body dementia, quetiapine is less likely to exacerbate parkinsonian symptoms.

Similarly, the patient with preexisting schizophrenia may have difficulty in understanding and adapting to an ICU stay. Preemptive behavioral measures should be taken to make the ICU as familiar and comfortable as possible.

Inadequately controlled pain, panic-like anxiety, and a sense of hopelessness resulting from depression can also present with agitation. Anxiety and depression are discussed in Chapters 158 and 159, respectively. Once the trigger for agitation is understood, the appropriate course of treatment is often relatively straightforward. Table 157.9 compares and contrasts several diagnostic traits characteristic of different causes of agitation.

*a* Except when due to strokes, when the onset is acute.

*b* Lewy body dementia often presents with a waxing and waning course imposed on an overall progressive decline. Vascular dementia follows a stepwise pattern, worsening with each successive stroke.

*c* Except when complicated by catatonia.

Various substance-withdrawal syndromes may present with agitation and delirium. These often require specific treatment (usually featuring replacement of the dependence-inducing agent and gradual taper) and are covered in Chapter 126.
NONPHARMACOLOGIC TREATMENT OF AGITATION

Despite all efforts to curtail agitated or disruptive behavior, some patients may ultimately require physical intervention to prevent injury to themselves or hospital staff. Interventions range from relatively unobtrusive (e.g., use of mitts to prevent interference with equipment or constant observation to minimize wandering) to more restrictive (e.g., soft limb restraints, Posey vests, four-point restraints) [28]. Most states and individual institutions have protocols governing the application and documentation of such procedures. Since the application of physical restraints can, in itself, be disquieting to the patient, such intervention should be accompanied by the administration of sedating medication.
LONG-TERM SEQUELAE

Patients diagnosed with delirium are at greater risk for a multitude of neuropsychiatric sequelae long after their discharge from the hospital. Multiple studies have demonstrated increased risk of longstanding cognitive impairment in delirious patients when compared to matched controls [67–69]; one study reported that a diagnosis of delirium resulted in an almost doubled risk of cognitive impairment at 2 years [70]. A review of the available literature by Jackson and colleagues concluded that the presence of delirium (regardless of severity or duration) predicts a greater risk of long-term cognitive impairment, including the development of dementia [71]. Posttraumatic stress disorder (PTSD) has been reported in up to 44% of patients admitted to the ICU [72]. While PTSD may result from the experience of actual physical experiences in the ICU, it has also been reported to occur as the sole result of frightening, hallucinatory, or delusional symptoms experienced in the context of delirium [73].
Agitation in the ICU patient jeopardizes the immediate safety of the patient and may signify a potentially unidentified pathologic process. Delirium is the most frequent cause of agitation and is associated with poorer outcomes across multiple facets of patient care. Careful evaluation of possible causes of delirium is vital, since its only definitive cure is identification and treatment of the responsible underlying condition. Management may involve both pharmacologic and environmental measures, with manipulation of the dopaminergic and cholinergic axes, the primary targets of pharmacologic intervention.

Agitation may also be a symptom of other psychiatric disorders. Preexisting diagnoses of dementia, depression, or psychosis do not rule out the presence of delirium; however, active delirium does rule out the possibility of being able to diagnose a new dementia, depression, or psychosis. Given this level of diagnostic primacy and its manifold associated deleterious sequelae, delirium should be at the cornerstone of any investigation of agitation in the ICU.

Diagnosis and Treatment of Anxiety in the Intensive Care Unit Patient

SHELLEY A. HOLMER • ROBERT M. TIGHE

Anxiety is a normal, adaptive biological response to threat. It occurs when a person feels helpless and apprehensive about an uncertain future due to a perceived inability to predict or control a desired outcome. In contrast, pathological anxiety is normal anxiety run amok. It occurs spontaneously or amid usually benign circumstances, is excessive in intensity or duration, and impairs functioning and behavior. Anxiety manifests in a variety of ways, resulting in physical, affective, behavioral, and cognitive symptoms and signs (Table 158.1).

Patients admitted to the intensive care unit (ICU) commonly experience anxiety in response to pain, invasive procedures, an unfamiliar setting, and the fear of death. In moderation, anxiety can promote healthful behaviors, just as pain can lead to protection from future injury. In excess, however, anxiety can complicate diagnosis, interfere with treatment, and contribute to poor outcomes by increasing both morbidity and mortality. Anxiety can complicate the clinical picture, as symptoms and signs of many medical problems overlap with those of anxiety (e.g., chest pain, palpitations, tachycardia, diaphoresis, tremulousness). Overwrought patients may refuse tests or procedures they fear will cause pain or will lead to bad news. Patients with phobias of blood, needles, and confined spaces (e.g., computed tomography and magnetic resonance imaging machines) may forego necessary interventions. Pathological anxiety may contribute to the need for ICU admission.

This chapter reviews the physiological concomitants of anxiety, medical causes of anxiety, critical medical conditions particularly affected by anxiety, anxiety disorders specific to the ICU setting, and the treatment of anxiety.

**PHYSIOLOGICAL EXPRESSIONS OF ANXIETY**

The physiological expressions of anxiety are myriad. By activating the *fight or flight response*, anxiety recruits the entire autonomic nervous system to respond to an unknown enemy. Multiple organ systems—cardiovascular, respiratory, gastrointestinal, musculoskeletal, endocrine, immune—are involved. Anxiety increases blood levels of cortisol, prolactin, and growth hormone [1]. A disquieted patient has enhanced gastric motility and gastric secretions, vasoconstriction of the splanchnic and cutaneous circulations, and vasodilation of striated muscle groups [2]. Anxiety also has direct effects on the immune system: a reduction in the chemotaxis of lymphocytes and neutrophils, a decrease in the phagocytic ability of neutrophils, and an increase in plasma levels of tumor necrosis factor $\alpha$ and superoxide anions [3]. This suggests complex physiological effects of anxiety for the critically ill.

The organ systems adversely affected by anxiety of most concern to the intensivist are the cardiovascular and respiratory systems. Anxiety affects the cardiovascular system by altering normal autonomic tone, manifested as increases in heart rate, blood pressure, cardiac output, and cardiac irritability. The stress of simply being hospitalized augments urinary
excretion of catecholamines, which represents activation of the sympathetic nervous system and contributes to cardiac arrhythmias [4]. In the fight or flight response, augmentation of cardiac output prevents cardiovascular collapse, but, in heart failure and myocardial infarction (MI), excessive cardiac output can be detrimental. Anxiety increases respiratory rate, tidal volume, and airway resistance and can induce hyperventilation and syncope. These data suggest that anxiety, while exacting a psychological toll, also significantly alters cardiorespiratory physiology, especially in the critical care setting.
MEDICAL CAUSES OF ANXIETY

Because failure to identify and treat organic (i.e., medical or secondary) causes of anxiety can result in increased morbidity and mortality, the distinction between organic and functional (i.e., psychiatric or primary) causes is vitally important. The presence of an organic cause is suggested when anxiety occurs autonomously in the absence of an apparent psychologically charged situation or of a discrete physical event (e.g., acute pain or tachyarrhythmia). However, in any given patient, determination of what constitutes an appropriate or sufficient psychological precipitant for anxiety is difficult. Life history, cultural background, and prior behavioral conditioning are often unknown to clinicians in the fast-paced ICU setting. Therefore, when anxiety is present and no clear psychological or medical cause is obvious, a thorough search for an organic cause is indicated.

Anxiety is a symptom of hundreds of medical conditions; Table 158.2 provides a list of conditions common in the ICU. Two syndromes that are particularly difficult to distinguish from primary anxiety are delirium and substance withdrawal.

Delirium

Treating the delirious patient solely with anxiolytics (e.g., benzodiazepines) can exacerbate confusion, so it is important to distinguish delirium from anxiety by doing a brief cognitive examination. In delirium, performance of tasks of attention, orientation, memory, and language is often impaired; rarely does an anxious patient have these deficits. By definition, delirium always has a medical cause; therefore, determination of its cause, rather than simply treating its symptoms, is vital. Recognition and management of delirium are discussed in Chapter 157.

Substance Withdrawal Syndromes

Because withdrawal from central nervous system depressants (e.g., opioids, benzodiazepines, alcohol) can be life-threatening, it should always be high on the differential diagnosis of anxiety. This diagnosis can be missed because patients either underreport their substance use or are unable to communicate. Patients can also withdraw from sedatives and opioids prescribed during a lengthy period of mechanical ventilation. Recognition and treatment of withdrawal syndromes are discussed in Chapter 126.
SCENARIOS IN WHICH ANXIETY SIGNIFICANTLY AFFECTS OUTCOMES OF MEDICAL ILLNESS

Acute Myocardial Infarction

As heart disease remains the leading cause of mortality in the United States, *acute coronary syndrome* (ACS) is a common reason for admission to the coronary care unit (CCU). Prevention and treatment have focused on awareness and alteration of traditional risk factors (e.g., hyperlipidemia, hypertension, family history). A developing literature supports consideration of psychosocial factors as well, most frequently, anxiety, depression, and personality traits [5].

Anxiety is a frequent occurrence in the CCU, both related to MI itself and as a premorbid condition contributing to the development of MI [5,6]. Anxiety occurs in 20% to 50% of patients after MI [7,8]. The stress of being cared for in an ICU, particularly the relinquishing of control and privacy, in addition to dealing with a potentially life-threatening disease, contribute to anxiety in this setting [9]. Anxiety in the CCU after MI rises rapidly and peaks within the first 12 hours; declines during the next 36 hours; and then increases again as patients face transfer out of the CCU and ultimately discharge from the hospital [10]. Physicians and nurses often under-recognize anxiety and underestimate its severity after MI [11]. Anxiolysis should be an early consideration in post-MI patients.

Physiologically, anxiety impacts the cardiovascular system through several mechanisms. Most generally, it activates the sympathetic nervous system, which directly causes vasoconstriction, tachycardia, increased blood pressure, platelet activation, and potential for arrhythmia [12,13]. Heart rate variability (HRV), the ability the sympathetic and parasympathetic nervous systems have to regulate the cardiac pacemaker, is decreased in many patients with anxiety [14]. Decreased HRV in patients following MI has been consistently associated with mortality [15]. Overall, these physiological changes may explain why anxiety—especially phobic anxiety—has been directly linked to an increased risk for sudden death [16].

Anxiety also appears to influence other physiological processes associated with ACS, including the inflammatory response [17,18], impaired coagulation [19], platelet activity [20], and endothelial dysfunction [21,22]. In addition to direct physiological effects, anxiety may lead to poor cardiac outcomes through its effects on important risk-
Reducing recommendations after MI, including stress reduction, greater socialization, smoking cessation, and improved diet [23].

Two groups have demonstrated that anxiety, independent of depressive symptoms, is associated with in-hospital complications after acute MI, including recurrent ischemia, re-infarction, congestive heart failure, and ventricular arrhythmias [9,24]. Further trials are required to determine whether the effect of anxiety is “dose”-dependent and whether effective anxiety treatment improves cardiac outcomes. In the setting of acute MI, benzodiazepines have been shown to reduce anxiety, pain, and cardiovascular activation. Their use leads to a reduction of circulating catecholamines and may also cause coronary vasodilatation, prevent dysrhythmias, and retard platelet aggregation [25].

The correlation between anxiety and post-MI outcomes in the long term is more complex. Some [5,6,26], but not all [27,28], prospective trials demonstrate that high levels of anxiety predict cardiac events (e.g., unstable angina, re-infarction) and/or mortality. Definitive study of the association between anxiety and cardiac events remains difficult due to confounding factors. For example, depression is a well-established independent risk factor for poor post-MI outcomes [29]; it is difficult to isolate anxious patients who do not also exhibit symptoms of depression. Additionally, anxiety can have either beneficial or detrimental effects on important cardiac outcomes (e.g., physical activity and compliance with medical treatment). It leads to activation in some and avoidance in others depending on level of anxiety and personality characteristics.

Despite uncertainty about the role anxiety plays as a prognostic factor in patients with ACS, several psychological and pharmacological interventions have been studied. Many have shown a positive effect on psychiatric symptoms and quality of life but equivocal effects on cardiac outcomes and mortality [30,31]. Firm links between anxiety and hard cardiac endpoints over the long term remain unproven, limiting development of definitive treatment guidelines.

Weaning from Mechanical Ventilation

Respiratory failure and consequent need for mechanical ventilation are common causes of admission to the ICU. Nearly three fourths of patients resume spontaneous, unassisted breathing with little difficulty. However, patients who require prolonged mechanical ventilation have longer hospital stays, face higher morbidity and mortality, and require lengthier rehabilitation. Therefore, the goal is to wean patients as soon as possible,
as it is a central predictor of ICU survival.

Given the limitations of communication and easy fatigability in patients with critical illness, the evaluation of anxiety in this setting remains difficult. This difficulty extends to research efforts attempting to define the incidence of and factors leading to anxiety in the setting of ventilator weaning. Approximately 25% and 56% of patients experience symptoms of acute and chronic anxiety, respectively, related to mechanical ventilation [32]. The highest levels occur in patients intubated for primary respiratory disorders (e.g., chronic obstructive pulmonary disease [COPD]) and in those on prolonged (>22 days) artificial ventilation, the very groups who are most at risk for difficulty weaning from mechanical ventilation [33].

Although the physiological measures used to determine readiness to wean from the ventilator are well known and several of them have been studied closely in clinical trials, information about the effect of the patient’s psychological state, specifically anxiety, on weaning from the ventilator is scant. Given the extensive overlap between physiological effects of anxiety and those of respiratory muscle fatigue, it can be difficult to separate ventilator weaning failure from anxiety. Anxiety may cause shortness of breath and a fear of death or abandonment, especially as ventilatory support is withdrawn. This can stimulate the sympathetic nervous system; cause bronchoconstriction; and increase airway resistance, work of breathing, and oxygen demand. This cascade can become a perpetuating cycle of anxiety, muscle fatigue, and thus weaning failure. Furthermore, the cascade of anxiety worsens with each additional ventilator weaning failure [34].

Anxiety should be considered for all patients during the weaning process, especially those who are intubated for primary respiratory causes and for a prolonged period. Given the paucity of data regarding the effect of anxiety on ventilator weaning, no clear treatment guidelines exist; however, it is well appreciated that weaning should be approached from a multidisciplinary standpoint. Treatment includes pharmacological, environmental, and educational approaches; it is enhanced when patient, family, physicians, and nurses are involved in the decision to wean and in the process of weaning.

Because anxiety and respiratory distress due to fatiguing respiratory muscles can produce similar cardiorespiratory manifestations, disentangling the two is critical. Only if one is convinced that anxiety is the cause should one consider pharmacotherapy for anxiety because pharmacotherapy with benzodiazepines can potentially prolong weaning due to suppression of respiratory drive. (see Chapter 168). Although this class of medications is associated with respiratory suppression and altered level of consciousness and may lead to drug-induced delirium, benzodiazepines can be quite effective when used judiciously in the
correct setting. Neuroleptics are less associated with respiratory suppression and may be more beneficial than benzodiazepines, especially for patients whose weaning failure is due to fear or delirious agitation.

In addition to benzodiazepines and neuroleptics, dexmedetomidine, an $\alpha_2$-adrenergic receptor agonist, is increasingly being used. This agent causes a rapid onset of sedation and analgesia but not respiratory suppression [35]. The lack of respiratory-suppressant effects allows patients to be extubated while remaining on dexmedetomidine, whereas benzodiazepines require discontinuation or reduction prior to extubation. Studies suggest that dexmedetomidine reduces both the length of ICU stay and time to extubation [36]. The greater success in extubation appears to be more pronounced in patients who had failed previous conventional extubation attempts [37]. Therefore, dexmedetomidine is a reasonable option for anxious patients who are at high risk for ventilator weaning failure.

Non-pharmacological efforts are critical to successful weaning. Nursing should remain as consistent as possible with an individual patient; during active weaning, a 1:1 nurse-to-patient ratio should be maintained. Weaning is more successful when patients are aware of their environment and engaged in discussions of the plan and process of weaning. Patients should be told and reminded that weaning without extubation does not represent a failure but is part of the process. Music therapy has been associated with decreased anxiety in ICU patients and reductions in both the frequency and the intensity of sedation and may facilitate weaning [38]. Finally, appropriate engagement of family members in the process of weaning should be considered.
ANXIETY DISORDERS SPECIFIC TO THE INTENSIVE CARE UNIT

Patients with a variety of anxiety disorders present to the ICU. Symptoms associated with these conditions can be exacerbated by the acute medical or surgical problem that led to the ICU admission. In addition, medications used to treat a pre-existing anxiety disorder may be discontinued on admission, or their bioavailability may be altered by interactions with newly prescribed medications. Both discontinuation and pharmacokinetic changes may significantly worsen pre-existing primary anxiety disorders. In addition to exacerbating established psychiatric illnesses, the experience of the ICU can lead to new, longstanding anxiety disorders. Anxiety disorders particularly relevant in the ICU include acute and posttraumatic stress disorders and panic disorder.

Acute and Posttraumatic Stress Disorders

The experience of treatment in the ICU—which includes frightening confusion, painful invasive procedures, and fear of death—can be traumatic for many patients. Often, especially in the surgical ICU, patients are admitted due to a traumatic event (e.g., motor vehicle collision, severe burn, and assault). These circumstances predispose patients to the development of acute stress disorder (ASD) and posttraumatic stress disorder (PTSD).

Diagnosis of both ASD and PTSD requires clinically significant distress following exposure to actual or threatened death, serious injury, or sexual violation. Symptoms are clustered into four categories: re-experiencing, avoidance, negative thoughts/mood, and arousal [39]. Re-experiencing manifests in dreams, intrusive memories, flashbacks, or intense distress when exposed to reminders of the event. Distressing memories, thoughts, feelings, or external reminders of the event may be avoided. Negative thoughts/mood may include a distorted sense of blame of self or others, diminished interest in activities, or an inability to remember key aspects of the event. Arousal symptoms can include aggressive, reckless, or self-destructive behavior; sleep disturbances; and hypervigilance. For a diagnosis of ASD, these symptoms must occur within the first month after the trauma; if symptoms persist beyond 1 month, a diagnosis of PTSD should be considered.

Some patients develop syndromes consistent with both ASD and PTSD consequent to events that occur in the ICU. One out of five patients
exhibits clinically significant PTSD symptoms in the first 12 months after ICU discharge [40], significantly higher than the 3.5% prevalence of PTSD in the general population [41]. The risk of developing ASD and PTSD is presumed to be even higher in patients who are admitted to the ICU after a trauma.

ICU-related PTSD has been associated with worse health-related quality of life [42]. Specifically, PTSD secondary to acute coronary syndrome has been associated with a doubling of risk for death and recurrent cardiac events [43].

The most robust risks for ICU-related PTSD are pre-existing psychiatric conditions, greater ICU benzodiazepine administration, and early memories of in-ICU frightening experiences [40,44]. The positive correlation between benzodiazepine use and PTSD may be due to the need for higher doses of these medications in patients with pre-existing psychiatric conditions. Another possibility is that benzodiazepines can exacerbate delirium, which has been implicated as an independent risk factor for PTSD in some [45], but not all [46], studies. Delirium-associated delusions, hallucinations, and agitation requiring physical restraint may lead to both disturbing and false memories of the ICU stay, which have been correlated with higher rates of PTSD and worse health-related quality of life [47,48]. Therefore, interventions that target delirium, disorientation, and faulty reality testing may prevent PTSD.

Both behavioral and pharmacological interventions to prevent PTSD have been studied. Although there is a lack of randomized controlled trials to support their widespread adoption, both bedside psychological interventions (e.g., educational interventions, counselling, and stress management) and daily-event diaries to improve factual memory of time spent in intensive care have shown benefit in curtailing the development of PTSD [49–51].

Studies of psychopharmacological intervention for the prevention of PTSD have yielded mixed results. Several studies have demonstrated a decrease in the prevalence of PTSD for critically ill patients treated with stress doses of corticosteroids, which are thought to have an effect on traumatic-memory retrieval [52–54]. There is also evidence that treatment with β-receptor antagonists may protect against the development of PTSD, perhaps by blocking catecholamines, which enhance memory of emotionally arousing experiences [55,56]. However, this benefit was not seen in a randomized controlled trial of critically ill patients [57]. A recent meta-analysis of prophylactic treatment for PTSD in the general population showed no benefit with β-receptor antagonists and some potential benefit with corticosteroids [58].

In the ICU, acute trauma should be treated with supportive reassurance and symptom-targeted medications. Clinicians should identify and treat delirium, make efforts to reduce unnecessary sedation,
and help orient patients to what is happening around them. A recent study identified other modifiable predictors of PTSD, including memories about pain, lack of control, and inability to express needs [59]. These can be addressed with appropriate pain assessment and management, allowing patients more choices in their care, and helping patients to communicate (e.g., using Passy-Muir valves in tracheostomized patients). Psychiatric consultation can be useful for both acute management and recommendations for outpatient treatment, especially in patients with pre-existing psychiatric illnesses.

Panic Disorder

Panic disorder is one of the most common psychiatric disorders in patients who are high users of medical services. The risk for development of panic disorder is higher in patients with migraine, mitral valve prolapse, asthma, and COPD [60]. As defined by the Diagnostic and Statistical Manual of Mental Disorders [39], a panic attack is a discrete period of fear or discomfort that develops suddenly, reaches a peak within 10 minutes, and is associated with the symptoms listed in Table 158.3. Panic disorder consists of recurrent panic attacks accompanied by persistent fear of having additional attacks, worry about the implications and consequences of the episodes, and a significant change in behavior related to the attacks. Many panic-disordered patients are hypervigilant to internal bodily stimuli, and some fear that their attacks indicate the presence of an undiagnosed, life-threatening illness. These concerns are assuaged only when the panic disorder is accurately diagnosed and effectively treated.

Risks for developing panic attacks include separation, disruption of important relationships, and medical illness—all endemic in the ICU. Timely diagnosis and treatment of panic disorder can circumvent unnecessary medical procedures and decrease morbidity and mortality. Because its presentation is similar to that of several medical conditions (e.g., stroke, MI, respiratory compromise, gastrointestinal conditions), especially in the ICU, panic disorder must be considered a diagnosis of exclusion. It is important to recognize panic attacks in the ICU setting not only to avoid misdiagnosis, but also because the physiological consequences of panic may exacerbate symptoms of pre-existing medical conditions and lead to more frequent medical hospitalizations. Emerging evidence also shows an association between panic disorder and post-ICU cardiovascular outcomes. Panic disorder is independently associated with incident coronary heart disease, MI, and major adverse cardiac events [61]. Panic disorder is also associated with an increased incidence of arrhythmias (e.g., atrial fibrillation), a frequent complication and reason for admission to the ICU [62]. The pathophysiology underlying these associations remains unknown.

Treatment for panic disorder includes psychotherapy and medication. Cognitive-behavioral techniques (e.g., psychoeducation, anxiety management skills, cognitive reframing, and exposure to somatic cues) have been well studied. Benzodiazepines and antidepressants—specifically the selective serotonin reuptake inhibitors (SSRIs)—are the standard of care for the psychopharmacological management of panic disorder.
TREATMENT OF ANXIETY IN THE INTENSIVE CARE UNIT

Treatments for anxiety in the ICU include both non-pharmacological and pharmacological options. Additionally, the stress placed on medical and nursing staff attending to anxious patients in an emotionally charged treatment setting where family members also experience poor sleep and anxiety must be acknowledged and addressed to improve the overall care of patients in the ICU [63].

Non-pharmacological methods that have been explored include education, environmental manipulation, muscle relaxation, and music therapy. As ICUs have become increasingly focused on providing patient-centered care to improve outcomes, these non-pharmacological modalities are more frequently utilized and studied. Additionally, non-pharmacological modalities have the added benefits of limiting adverse side effects related to sedative-hypnotics in critically ill patients. Patients should be made aware of their clinical situation and oriented to their environment. Provision of ambient light, a clock, and a calendar promotes accurate orientation and a normal sleep–wake cycle. In addition, to foster a sense of control and mastery of their situation, patients should be made an integral part of decision-making. In a randomized controlled trial of 41 CCU patients, those who were given choices about family visits, daily hygiene schedule, physical activity, and their room environment enjoyed significant improvement in anxiety and depression measures after 48 hours [64]. Additionally, research efforts have focused on measures to improve anxiety through audiovisual aids. Spiva et al. [65] demonstrated that use of guided imagery—60 minutes of images and voice recordings providing instructions on patient relaxation—was associated with reductions in Richmond Agitation-Sedation Scale (RASS) score, use of sedatives and analgesics, days requiring mechanical ventilation, and hospital length of stay. Music therapy also has been increasingly utilized. Chlan et al. [38] demonstrated a significant association between the use of music therapy and reductions in anxiety and frequency and intensity of sedation. Evaluation of multiple studies using music therapy clearly demonstrates a reduction in anxiety [66]. Studies also suggest that music therapy reduces respiratory rate and systolic blood pressure. Whether these physiological changes translate into reduced mortality or improved quality of life remains unknown.
Benzodiazepines represent the standard for anxiolysis in the ICU; of these, lorazepam is the most widely used. Available in an intravenous formulation, it undergoes little hepatic metabolism, has no active metabolites, and is more appropriate for use in patients with liver disease or with poor liver function. Lorazepam is also useful for long-term sedation in ventilated patients as it is not associated with heart block (as is propofol) or with wide body storage (as is midazolam). However, intravenous formulations of lorazepam contain propylene glycol, and prolonged use of high doses can precipitate an osmolar-gap acidosis.

Another agent of recent interest and increasingly used in the ICU is dexmedetomidine, which inhibits the central and peripheral effects of norepinephrine and epinephrine, resulting in sedation and analgesia. While dexmedetomidine may cause bradycardia and hypotension, trial data suggest that clinically significant adverse hemodynamic changes are rare [35]. Dexmedetomidine and propofol performed equally in pain and anxiety reduction and sleep/rest promotion [67].

Other agents that may prove useful in the anxious patient are SSRIs, neuroleptic agents, and propofol. SSRIs have been shown to decrease the sense of dyspnea in anxious patients with COPD [68]. Neuroleptics are beneficial in patients who are fearful, delirious, or so anxious that they are nearly psychotic [69]. Use of neuroleptic agents is discussed in Chapter 157. Propofol continues to be the most commonly used medication for sedation in the ICU but is impractical for routine anxiolysis given its significant respiratory-depressant effects. Table 158.4 contrasts various agents commonly used to quell anxiety in critically ill patients. Table 158.5 presents a summary of randomized trials of anxiety treatments in critically ill patients.

<p>| TABLE 158.4 Some Intravenous Medications for the Treatment of Anxiety |

CONCLUSION

Ubiquitous in the ICU, anxiety has a broad range of physiological and psychological consequences. Although it can be difficult to diagnose in the acutely ill, current evidence suggests that identification and treatment of anxiety enhance patient comfort and compliance and improve morbidity and mortality. Therefore, anxiety should be routinely assessed in critically ill patients. Psychiatric consultation should be considered whenever anxiety complicates the clinical course.

In the intensive care unit (ICU), depression can be a psychologic reaction to an acute medical illness, a manifestation of a primary affective disorder, or a mood disorder associated with a specific organic disease or its treatment. For example, depression is associated with the development and the progression of, and with worse prognosis in, coronary heart disease (CHD) [1]. In fact, in 2014, the American Heart Association recommended that depression be considered a risk factor for adverse outcomes in patients with acute coronary syndrome (ACS) [2]. In addition, depression is a frequent complication after stroke and is associated with greater disability and mortality [3].

In this chapter, the term depression refers not to being transiently sad, discouraged, disappointed, despondent, or grief-stricken, but to major depressive disorder (MDD), defined in the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) [4] as a syndrome of distinct and persistent dysphoria associated with neurovegetative changes and functional impairment. Many physicians believe that depression is appropriate in the ICU because severe illness can be devastating to a person’s life. However, we believe that whereas being dispirited may be an understandable response to critical illness, having a depressive disorder is not; therefore, it is always important to treat the latter. In fact, compelling evidence shows that untreated depression is associated with morbidity and mortality from cardiac and neurologic
conditions and has detrimental effects on other, perhaps all, organ systems.

In this chapter, we focus on the links between depressive and medical conditions and the diagnosis, evaluation, and treatment of depression in critically ill patients.

DIAGNOSIS OF DEPRESSION

Important questions for the intensivist are “What is depression?” and “What does a patient experiencing depression look like in the ICU?” To qualify for a diagnosis of MDD according to the DSM-5, a patient must have five of the nine symptoms listed in Table 159.1, one of which must be either depressed mood or anhedonia, most of the day, nearly every day, for at least 2 weeks. The mnemonic—SIG: E CAPS (where SIG [abbreviation for the Latin, signa] refers to the instructions on a prescription, E refers to energy, and CAPS refers to capsules)—is a helpful guide to remember the eight neurovegetative symptoms associated with depressed mood. The mnemonic—ABCs of depression—portrays more richly the myriad affective, behavioral, and cognitive aspects of the condition (Table 159.2). Each symptom should be asked about, and questions about suicide should be raised directly. If a patient has thoughts of suicide, he or she should be asked whether there is a specific plan; the physician should then make a judgment about the likelihood of the patient’s acting on the plan. If an active plan for suicide exists, psychiatric consultation is imperative (see Chapter 160). In medically ill patients, holding the cardinal symptoms of depressed mood and anhedonia to the strict requirement of presence most of the day, nearly every day, for at least 2 weeks is critical to avoid overdiagnosis of depression in medically ill patients.

Patients Who are Unable to Speak

It may be particularly difficult to diagnose depression in a patient who is being mechanically ventilated or has aphasia. Methods of assessing depression in these patients are summarized in Table 159.3. Some tracheostomized patients may be able to use a Passy-Muir valve. See Chapter 169 on Respiratory Adjunct Therapy for an indepth discussion of Passy-Muir valve use. Alternatively, electronic voice-output communication aids may be used. These devices pair prerecorded messages or synthesized speech with labeled icons; patients communicate messages by touching buttons on display screens or on touch-sensitive keyboards. Speech pathologists have knowledge of and access to such

DIFFERENTIAL DIAGNOSIS OF DEPRESSION

Causes Related to Medical Conditions

A variety of medical illnesses can cause, contribute to, or worsen affective symptoms and disorders (Table 159.4). Clues that depression is due to a medical illness include older age at onset of symptoms; lower incidence of a family history of depression; and changes in personality and cognition. A thorough history (including a review of systems); physical (including neurologic) examination; and laboratory testing can distinguish between primary (i.e., due to a psychiatric condition) and secondary (i.e., due to a medical condition) causes of depression. For secondary causes, treatment of the underlying illness is usually more effective than is the use of psychotropic medications.

Perhaps the most important differential diagnosis to consider in a patient who appears to have MDD is hypoactive delirium. The key feature that distinguishes it from depression is inattention (i.e., an inability to focus and sustain alertness on a given stimulus and to resist distraction by other stimuli). Delirium is discussed in Chapter 157.

### Causes Related to Medical Treatments

The pharmacologic agents most often responsible for depression in the ICU are antihypertensives, β-blockers, antiarrhythmics, and steroids (Table 159.5). Some medications may cause depression only after several weeks or even months of continuous use. If a drug regimen or a dosage increase appears to be temporally related to the patient’s depression, the dose should be lowered or the medication eliminated entirely. If the medication cannot be stopped without serious risk to the patient, the depression should be treated.

Steroids

Depression, mania, psychosis, and delirium are frequent side effects of corticosteroid therapy. Mood symptoms are dose-dependent and usually occur within the first 2 weeks of therapy, although they can arise on the first day. A practical rule of thumb holds that neuropsychiatric adverse effects are common with prednisone ≥ 80 mg per day (or equivalent), uncommon ≤ 30 mg per day, and not uncommon in between. Although it has been suggested that women are more likely to develop steroid-induced adverse effects, the apparent increased frequency may be due to the higher prevalence of rheumatologic diseases in women. Corticosteroid-induced mood disorders are generally reversible with dosage reduction or discontinuation of the medication.
LABORATORY EVALUATION OF DEPRESSION

Although the clinical interview and mental status examination are the most important components of psychiatric diagnosis, the use of laboratory tests is essential to exclude organic causes of depression. Although there is no consensus on the laboratory tests necessary in a patient with new-onset mood disorder, Table 159.6 lists those tests that should be considered. Thyroid-stimulating hormone is not on this list because many critically ill patients have abnormal thyroid biochemical profiles but do not have intrinsic thyroid disease. Syphilis and hypovitaminosis are rarely the sole causes of depression; tests for these conditions should be ordered only when there is a specific indication for them. Neuroimaging, electroencephalography, and cerebrospinal fluid analysis are relatively indicated in patients with new-onset psychiatric symptoms, altered cognition, new neurologic symptoms, seizures, and fever. The more of these features a patient has, the more important these additional tests become.

TREATMENT OF DEPRESSION

Patients who meet the criteria for MDD are usually treated with a somatic therapy (including pharmacotherapy and electroconvulsive therapy [ECT]), alone or in combination with psychotherapy (Table 159.7). In critical care units, somatic therapies are the most widely used treatments for depression. Pharmacotherapy may be used in critical care units also for patients who have an adjustment disorder with depressed mood, particularly when these patients have several neurovegetative symptoms. A patient who is neither eating nor sleeping and lacks the energy to participate in his or her rehabilitation may be helped considerably by antidepressants, especially psychostimulants.

+, low; ++, moderate; +++ , high; ACh, anticholinergic effects; IR, immediate release; MAOIs, monoamine oxidase inhibitors; OH, orthostatic hypotension; SNRIs, serotonin–norepinephrine reuptake inhibitors; SR, sustained release; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants; XL, extended release.

Each type of pharmacotherapy has its own indications and contraindications. A useful guiding principle is to choose a medication with a side-effect profile that best fits a patient’s needs. For instance, a patient who is having trouble sleeping will benefit from a sedating antidepressant. Conversely, a patient who has severe psychomotor retardation may benefit from a more stimulating antidepressant. With
the exception of the psychostimulants, all antidepressants require approximately 4 to 6 weeks until full antidepressant effects are noted, although some response can occur in 1 to 2 weeks. Obviously, in critical care units, quicker effects are generally needed. Stimulants and ECT work more quickly, usually within several days. Patients with depression may also manifest considerable anxiety and may be helped by the use of an anxiolytic while awaiting response to an antidepressant. Depressed patients with psychosis (i.e., those with delusions or hallucinations) may need antipsychotics for symptom control.

### Psychostimulants

Psychostimulants have been used to treat depressive symptoms since their development in the 1930s, but they fell into disrepute when they became known as drugs of abuse in the 1950s and 1960s. Since then, however, there have been numerous reports on the use of stimulants in the treatment of depressed patients, particularly apathetic and geriatric patients. Thought to be particularly effective in patients with cancer and stroke, their rapid onset is of great use in any setting where speed of recovery is crucial, including the ICU.

The psychostimulants most commonly used are dextroamphetamine (Dexedrine) and methylphenidate (Ritalin). Both appear to work through the direct neuronal release of dopamine and norepinephrine; dextroamphetamine blocks catecholamine reuptake and weakly inhibits monoamine oxidase. Both of these psychostimulants are predominantly excreted by the kidneys, although dextroamphetamine also undergoes a complex biotransformation.

The usual effects of stimulants are to increase motor behavior, increase arousal, and decrease appetite; however, in patients who are anorexic on the basis of depression, appetite is paradoxically increased, likely through dopaminergic stimulation of the nucleus accumbens. Their antidepressant effect is usually evident in the first 2 days of treatment, if not earlier. Stimulants do not have anticholinergic effects or cause orthostatic hypotension. They can increase heart rate and blood pressure and can cause coronary spasm and cardiac arrhythmias; however, these effects are rare (even with preexisting cardiac abnormalities) at the low doses (5 to 20 mg per day) usually used for the treatment of depression. In fact, stimulants have been used safely and effectively in a broad spectrum of patients, including those with critical illness, and have shown little potential for abuse or dependence. Contraindications to stimulant use include seizures, delirium, psychosis, significant hypertension, unstable angina, pregnancy, and the concurrent use of α-methyldopa (which becomes a sympathoamine when metabolized), monoamine oxidase inhibitors (MAOIs), or bronchodilators.
Psychostimulants should be the first consideration when treating depression for critically ill patients. Patients are started on 5 mg of methylphenidate or 2.5 to 5 mg of dextroamphetamine in the morning. The dose is increased by 5 mg per day (for methylphenidate) or 2.5 to 5 mg per day (for dextroamphetamine) until a therapeutic effect is detected or until a maximum dose of 20 mg has been reached. Heart rate and blood pressure should be monitored. Stimulants are usually given for at least 1 to 2 weeks after depressive symptoms have fully remitted. In most cases, after stimulants are stopped, depression does not recur.

Stimulants taken in overdose may cause seizures, coma, hallucinations, paranoia, hyperthermia, hypertension, cardiac arrhythmias, angina, and circulatory collapse. The major treatment for overdose is to acidify the urine (which enhances renal excretion) and to use supportive measures for all other abnormalities.

Modafinil (Provigil)—a wakefulness-promoting medication approved for narcolepsy, shift work sleep disorder, and obstructive sleep apnea/hypopnea syndrome—may be a beneficial alternative to the psychostimulants.

Selective Serotonin Reuptake Inhibitors

The selective serotonin reuptake inhibitors (SSRIs) cause a potent and selective blockade of serotonin reuptake. Since the introduction of fluoxetine (Prozac) in 1987, SSRIs have become the most widely prescribed class of antidepressants. Other SSRIs include sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), and escitalopram (Lexapro). They are far less anticholinergic, antihistaminergic, and anti-α₁-adrenergic than the older tricyclic antidepressants (TCAs) and, therefore, are associated with far fewer side effects. They also have fewer cardiovascular effects and do not commonly cause orthostatic hypotension.

Pharmacokinetics

SSRIs are well absorbed from the gastrointestinal tract, and absorption is generally unaffected by food and antacids. They have a large volume of distribution and are highly protein-bound. They are extensively metabolized in the liver, where they are oxidized, methylated, and conjugated. The elimination half-lives of sertraline, paroxetine, fluvoxamine, and citalopram are approximately 1 day (although sertraline has a mildly active metabolite with a half-life of 66 hours); this allows once-a-day dosing. Fluoxetine has a half-life of 2 to 3 days and a highly active metabolite (norfluoxetine) with a mean half-life of 6.1 days. Fluoxetine takes a much longer time to reach steady state and, more
importantly for drug overdoses, can take weeks to months to be fully cleared. Elimination half-lives are dose-dependent (i.e., higher doses and lengthier usage are associated with higher plasma levels and longer half-lives). SSRIs show wide inter-individual variation in pharmacokinetics and do not have a clearly established dose–response curve.

Metabolic Impairment

Fluoxetine, sertraline, fluvoxamine, and citalopram are unaffected by renal dysfunction. Paroxetine, although minimally excreted in the urine (like other SSRIs), shows increased plasma concentrations in the setting of renal disease. Fluoxetine, sertraline, paroxetine, and citalopram doses should be reduced by at least half in patients with liver disease. Fluvoxamine has been used in patients with cirrhosis and hepatic encephalopathy without adverse effects. The hepatic clearance, not the plasma concentration, of fluvoxamine is affected by cirrhosis. Therefore, the dosage frequency, rather than the total dosage, should be altered. In elderly individuals, fluoxetine does not have altered pharmacokinetics; in contrast, sertraline and paroxetine have increased plasma levels and slower clearance. Although citalopram has a 30% longer half-life in the elderly, the frequency and severity of side effects are not higher in this group.

Side Effects

SSRIs can cause tremulousness, agitation, irritability, insomnia, anorexia, nausea, vomiting, diarrhea, excess sweating, and sexual dysfunction (i.e., decreased libido, and erectile and orgasmic dysfunction). The syndrome of inappropriate antidiuretic hormone is an uncommon adverse effect reported with all of the SSRIs, especially in critically ill patients; other causes of hyponatremia should be sought before attributing the metabolic derangement to the SSRI. The SSRIs do not typically cause clinically significant changes in heart rate, blood pressure, or the electrocardiogram (ECG). Citalopram, however, has been associated with dysrhythmias, including torsade de pointes (especially in the setting of QT prolongation), and doses should generally not exceed 40 mg per day (20 mg per day in patients >60 years). There is also concern about escitalopram and dysrhythmias as well. Overdoses of SSRIs are discussed in Chapter 104.
Drug–Drug Interactions

The SSRIs are extensively metabolized by the cytochrome P450 system. All of them also inhibit various isoenzymes in this system and consequently raise the plasma levels of other drugs metabolized by those isoenzymes; sertraline, citalopram, and escitalopram do this the least. The interactions most likely to occur in an ICU are listed in Table 159.8. Attention to drug dosage can mitigate the harmful effects of these interactions.

Drug Discontinuation

The usually mild symptoms of the SSRI discontinuation syndrome (e.g., headache, dizziness, myalgias, and nausea) are generally eclipsed by more pressing issues in critically ill patients.

Serotonin–Norepinephrine Reuptake Inhibitors

Venlafaxine

Venlafaxine (Effexor) is a selective serotonin and norepinephrine reuptake inhibitor (SNRI). It is very similar to the SSRIs in most clinical and pharmacologic aspects. It has few anti-$\alpha_1$-adrenergic, anticholinergic, and antihistaminergic side effects. Venlafaxine has a 6- to 8-hour half-life and must be given two to three times daily, but an extended-release preparation (Effexor XR) allows once-daily dosing. It causes a dose-dependent increase in systolic and diastolic blood pressure (up to 7.5 mm Hg), occurring in approximately 7% of patients taking daily doses between 200 and 300 mg and in up to 13% of patients taking >300 mg [5]. The major active metabolite of venlafaxine, desvenlafaxine, is now available as a primary compound (Pristiq); its advantages over its parent compound are uncertain.

Duloxetine

Another SNRI, duloxetine (Cymbalta) is indicated for MDD, generalized anxiety disorder, diabetic neuropathy, and fibromyalgia. Its half-life is 12 hours, and it can be given once or twice daily. Like venlafaxine, it has little effect on $\alpha_1$-adrenergic, cholinergic, and histaminergic receptors. Any therapeutic advantage over venlafaxine, particularly for critically ill patients, has yet to be demonstrated.

Levomilnacipran

The latest SNRI to be approved, levomilnacipran (Fetzima) is the more active enantiomer of milnacipran. Levomilnacipran has an approximately twofold greater potency for norepinephrine relative to serotonin reuptake inhibition at low doses, although at higher doses, these potencies are the
same [6]. It is not known to have affinity for adrenergic, muscarinic, or histaminergic receptors [6]. Levomilnacipran is delivered in an extended-release capsule given once daily in a recommended dose range of 40 mg to 120 mg. Because levomilnacipran is metabolized by cytochrome P450 3A4, dose reduction is necessary when it is co-administered with CYP3A4 inhibitors. The half-life of the drug is approximately 12 hours. Elimination of levomilnacipran occurs renally. Dose reduction is recommended in patients with moderate to severe renal impairment; its use is not recommended for patients with end-stage renal disease [7]. Dose adjustment is not required in patients with hepatic insufficiency [8]. Adverse effects most commonly include hyperhidrosis, tachycardia, palpitations, nausea, vomiting, constipation, and erectile dysfunction. Levomilnacipran does not appear to prolong the QT interval, but it has been associated with orthostatic hypotension and minor increases in systolic and diastolic blood pressure.

**Atypical Antidepressants**

**Vortioxetine**

Approved in 2013, vortioxetine (Brintellix) is a serotonin reuptake inhibitor; a 5-HT_{1A} receptor full agonist; a 5-HT_{1B} receptor partial agonist; and a 5-HT_{1D}, 5-HT_{3A}, and 5-HT_{7} receptor antagonist [9,10]. With a half-life of approximately 66 hours [11], it is dosed once daily between 5 mg and 20 mg. No dose adjustment is needed in patients with mild to moderate hepatic impairment or in patients with mild to end-stage renal impairment [11]. Vortioxetine is metabolized by multiple cytochrome P450 enzymes, primarily 2D6. It has no active metabolites [12]. Vortioxetine has been found to be safe and effective in the geriatric population [13]. Its major side effects are nausea, vomiting, and constipation.

**Vilazodone**

Approved in 2011, vilazodone (Viibryd) is a serotonin reuptake inhibitor and 5-HT_{1A} partial agonist. Metabolized by the cytochrome P450 3A4 isozyme, vilazodone may need to be administered in lower dosages when combined with 3A4 inhibitors and in higher dosages when combined with 3A4 inducers [14]. No dose adjustment is recommended in patients with hepatic impairment [15]. Breakthrough seizures in a patient with a history of seizure disorder and seizure associated with serotonin syndrome in overdose have been reported with vilazodone [16,17]. Although few data exist, vilazodone has not been found to have an effect
on heart rate or cardiac conduction [18]. The most common adverse effects are insomnia, nausea, vomiting, and diarrhea [19].

Bupropion

A monocyclic ketone antidepressant, bupropion (Wellbutrin) blocks norepinephrine and dopamine reuptake. As such, it can be activating and used in place of psychostimulants for patients who cannot tolerate these agents or in whom they are contraindicated. Its major side effects are agitation, insomnia, tremulousness, nausea, vomiting, and diarrhea. The immediate-release formulation is associated with an increased risk of seizures, but this risk in the sustained-release (SR) and extended-release (XL) preparations is comparable to that associated with other antidepressants. It carries a low risk of cardiac toxicity, though, in overdose, sinus tachycardia and intraventricular conduction delays have been reported [20]. Bupropion has gained widespread use as an aid in smoking cessation.

Mirtazapine

Mirtazapine (Remeron) is an analog of the tetracyclic antidepressant, mianserin. As an antagonist at presynaptic and postsynaptic α₂-adrenergic receptors and at postsynaptic 5-HT₂ and 5-HT₃ receptors, it enhances both norepinephrine and serotonin transmission. It has few anticholinergic and anti-α₁-adrenergic effects. Mirtazapine is a potent histamine blocker and can cause significant sedation, an increase in appetite, and weight gain—a side-effect profile that is often exploited to advantage in medically ill patients. Mirtazapine is devoid of significant effects on the cytochrome P450 system, making it less apt to cause drug–drug interactions.

Tricyclic Antidepressants

TCAs work by blocking reuptake of norepinephrine and serotonin at presynaptic sites. The most common side effects of TCAs are sedation, orthostatic hypotension, and anticholinergic effects (including confusion, blurred vision, dry mouth, constipation, and urinary hesitancy or retention). The tertiary-amine parent compounds, amitriptyline (Elavil) and imipramine (Tofranil), are more apt to produce these adverse effects than are their respective secondary-amine metabolites, nortriptyline (Pameler) and desipramine (Norpramin).

Because of this extensive side-effect profile, including adverse effects on cardiac conduction and cardiac rhythm, the TCAs have largely been
eclipsed in recent times by the SSRIs and other newer agents, which are safer and better tolerated. TCAs are relatively contraindicated in patients with cardiac disease and are not recommended in the acute post-MI period. In fact, some data even suggest that TCAs may precipitate arrhythmias and sudden death in cohorts other than just the post-MI population [21].

As a result, it is relatively unusual to see a patient on a TCA at an antidepressant dose in the ICU and highly unusual to start a TCA in an ICU patient. TCAs are still used with some regularity for neuropathic pain syndromes; when used in this situation, doses are much lower than those used in depression treatment. Overdoses with TCAs may be treated in the ICU and are discussed in Chapter 104.

Monoamine Oxidase Inhibitors

The MAOIs (isocarboxazid [Marplan], phenelzine [Nardil], and tranylcypromine [Parnate]) work by blocking the oxidative deamination of biogenic amines (e.g., norepinephrine and serotonin) and have been used for the treatment of depression since the 1950s. MAOIs may cause a profound hypertensive crisis when a patient taking MAOIs also takes a sympathomimetic medication (e.g., reserpine, guanethidine, pseudoephedrine, and ephedrine) or ingests tyramine-containing foods (e.g., aged cheeses, pickled foods, and yeast extracts). Coadministration with opioids, particularly meperidine, also may lead to hypertensive crises and to elevated blood levels of meperidine and its neurotoxic metabolite, normeperidine. The use of β-blockers with MAOIs may lead to unopposed α-adrenergic activity and also cause severe hypertension. For these reasons, similar to TCAs, MAOIs are infrequently used in recent times, even by psychiatrists, and it would be highly unusual to begin an MAOI in an ICU patient. Overdoses with MAOIs may be treated in the ICU and are discussed in Chapter 104.

Pharmacologic Treatment of Depression in Heart Disease

Table 159.9 summarizes the studies of the effect of antidepressant treatment on psychiatric or cardiovascular outcome or both in patients with heart disease [22–28].

*aSymptoms of ≥7 days’ duration if there was ≥1 prior depressive episode, 14 days if not.

ACS, acute coronary syndrome; BDI, Beck Depression Inventory; CBT, cognitive-behavioral therapy; CM, clinical management; DSM-IV, Diagnostic and Statistical Manual of Mental Disorders, 4th edition; ICD-10, International Classification of Diseases, 10th edition; IPT, interpersonal therapy; LVEF, left ventricular ejection fraction; MDD, major depressive disorder; MI, myocardial infarction; PHQ, Patient Health Questionnaire; PVCs, premature ventricular contractions; QTc, QT interval corrected for heart rate; SSRI, selective serotonin reuptake inhibitor.

The Sertraline Antidepressant Heart Attack Randomized Trial (SADHART) was designed to evaluate only the safety and efficacy of sertraline, not its effect on cardiac outcomes. Nevertheless, the number of severe events (e.g., death, stroke, myocardial infarction [MI], recurrent angina, congestive heart failure [CHF]) was lower in patients treated with sertraline (14.5%) compared with those receiving placebo (22.4%) [22]. After a median follow-up of almost 7 years, baseline MDD severity and persistence of depression despite active or placebo treatment in the 6 months immediately after ACS independently predicted more than a doubling of mortality risk [29].

The Enhancing Recovery in Coronary Heart Disease Patients (ENRICHD) study was the first trial of the effect of depression treatment on mortality and reinfarction among post-MI patients [23]. The differential improvement of depression between the intervention and the usual-care groups was only modest and short-lived. Most notably, the
intervention yielded no cardiac benefits. This negative result may have occurred because many of the patients in the usual-care arm received antidepressant medication, thus potentially obscuring any between-group differences. In fact, a secondary analysis found that patients exposed to SSRIs had a lower risk of death or recurrent MI and of all-cause mortality compared to patients who did not take SSRIs [30]. In addition, patients with mild, transient depressions likely to have improved on their own were included in the study, and the treatment duration of 6 months may have been too short to discern a salutary effect.

Carney et al. undertook a subgroup analysis of patients with full (rather than modified) criteria for MDD or minor depression, a baseline Beck Depression Inventory (BDI) score ≥10, and a history of at least one episode of MDD and completed the follow-up evaluation 6 months after enrollment (i.e., those patients who completed the intervention) [31]. Although the difference in the mean change in BDI score from baseline to 6 months between groups was higher in this narrowed sample than in the entire cohort, this enhanced improvement did not translate into a survival benefit. Although patients who responded to the intervention experienced a reduction in mortality, the authors recommended caution in evaluating this finding, because it was based on small numbers.

The Myocardial Infarction and Depression-Intervention Trial (MIND-IT) examined the effects of antidepressant treatment on cardiac prognosis and the long-term course of depression [24]. The active treatment arm included three possibilities: randomization to mirtazapine or placebo; open treatment with citalopram; or treatment at the discretion of the treating psychiatrist. Those randomized to mirtazapine or placebo were given the option to switch to unblinded citalopram if there was no response after 8 weeks. Similar to ENRICHD, no significant differences between active treatment and usual care were found in depressive or cardiac outcome. In a separate analysis of just the patients who received mirtazapine, this agent yielded a therapeutic advantage over placebo [25]. In a three-way comparison of responders and nonresponders to either antidepressant (mirtazapine or citalopram) and patients who received no treatment, responders had the least cardiac events, followed by the untreated patients and then the nonresponders, leading the authors to suggest that persistence of depression may be the crucial “cardiotoxic” attribute of depressive illness, for which treatment resistance may be a marker [32].

In an 8-year follow-up of MIND-IT participants, there remained no difference between intervention and usual-care groups in cardiovascular
events and cardiac mortality [33]. However, those who received depression treatment, regardless of group assignment, experienced a reduction in all-cause mortality.

The Canadian Cardiac Randomized Evaluation of Antidepressant and Psychotherapy Efficacy (CREATE) trial, the first and only study designed to evaluate paired psychologic and pharmacologic interventions for depression treatment in CHD patients, failed to show a therapeutic advantage for interpersonal therapy, a manualized, short-term therapy focused on loss, grief, life transitions, interpersonal conflicts, and social isolation [26]. It demonstrated, however, that citalopram is an effective antidepressant in this population.

The lack of treatment benefit in the Sertraline Against Depression and Heart Disease in Chronic Heart Failure (SADHART-CHF) study may have been due to intervention and placebo groups both receiving nursing support, thus increasing the placebo response; the modest severity of depression; and the low average doses of sertraline used [27]. Secondary analyses showed that patients whose depression remitted had superior cardiac outcomes and greater improvement in physical and social function and quality of life [34,35].

In the Bypassing the Blues (BtB) study, the collaborative-care intervention involved a nurse care manager telephoning post-CABG patients to describe treatment options, including starting or adjusting antidepressant medications prescribed by their primary-care physicians [28]. A secondary analysis showed that the beneficial effect of the intervention was not because of adjustments in these medications [36], suggesting that other elements of the intervention (e.g., routine symptom monitoring, self-management of symptoms, psychiatric referral) may have been the active ingredients of collaborative care.

The first study of the prevention of depression in CHD patients, the Depression in Coronary Artery Disease (DECARD) trial randomized 240 patients with ACS, but without depression, to 1 year of escitalopram or placebo [37]. Two of 120 escitalopram-treated patients developed a depressive episode (ICD-10 criteria), whereas 10 of 119 (one randomized patient was ultimately excluded) placebo-treated patients did. The authors reported this as a statistically significant difference, but an accompanying editorial [38] suggested that the study was underpowered and raised concerns about its design, conduct, and reporting and about the cost and the prudence of exposing patients without depression to antidepressant medication.

Pharmacologic Treatment of Depression in Stroke

Tables 159.10 and 159.11 summarize findings from randomized, controlled trials of depression treatment and prevention, respectively, in
patients with cerebrovascular disease [39–59]. Double-blind treatment trials have demonstrated the safety and efficacy of antidepressants in treating poststroke depression; SSRIs are typically preferred owing to their more favorable side-effect profile. Although concern has been raised about the risk of hemorrhagic stroke with SSRIs, given their impact on platelet activity, a large database-derived case–control study of nearly 400,000 patients showed no association [60].

<td>Robinson, 2008 [43]</td>
<td>159 patients with MDD 10 d to 3 mo after stroke</td>
<td>Nefiracetam (^b) 600 or 900 mg/d vs. placebo</td>
<td>Both arms showed response rates &gt;70% and remission rates &gt;40%. Patients in the top quintile of HDRS scores showed a significant effect with 900 mg compared to 600 mg or placebo.</td>
</tr>
<tr>
<td>Williams, 2007 [44]</td>
<td>188 patients with poststroke depression</td>
<td>Nefiracetam (^b) 600 or 900 mg/d vs. placebo</td>
<td>Depression response and remission were more likely in the intervention group.</td>
</tr>
<tr>
<td>Choi-Kwon, 2006 [45]</td>
<td>152 poststroke patients with depression, emotional incontinence, or anger proneness</td>
<td>Fluoxetine 20 mg/d vs. placebo for 3 mo</td>
<td>Fluoxetine significantly improved emotional incontinence and anger proneness but not depression.</td>
</tr>
